CLINICAL LESSONS.

Motor Ataxia—Ataxia in a Child of Three Years, with Retained Muscle reflexes—Hysterical Ataxia, with Retained Muscle-reflexes.

BY S. WEIR MITCHELL, M.D., LL.D.,
OF PHILADELPHIA.

THE child, whose parents kindly permit me to show him to you, has a form of malady which I saw for the first time when I saw him last week. Here is a fine little man, well developed, exceedingly strong, and as intelligent as most children at his age. He is quite unable to stand alone. Even to sit alone seems difficult. No one will fail to note that he is ataxic from head to feet. The following notes of his condition at the present time are compiled from the examination-record made by Dr. John K. Mitchell and the very clearly written statement of the father.

P. Q., male, three years and five months of age.

Family history. The child's grandfather was addicted to alcohol. The parents are second-cousins and much alike in disposition and general characteristics. There is also some tuberculous history in the ancestry.

Previous history. The child was born normally at term. No instruments were used. The only thing attracting attention at the time of birth was "something unusual" about the little one's ankles. The physician said it was "all right," and the babe seemed otherwise like others; the child cried, kicked, nursed from the breast, etc. Owing to mammary abscesses the mother nursed the infant no more than four weeks. After that the child lived on non-sterilized cows' milk, and later on "malted milk" and other artificial foods until eight months of age, and with sustained good health.

At that time, however (eight months of age), it was taken on a railroad journey. It is supposed that "sour milk" was the cause of a severe attack of diarrhea, which resulted, at the end of the long trip or a few days later, in what the physician writes was "spurious hydrocephalus." Then the temperature was 103.5° F. The child threw its hands about, especially toward the head, and moaned a great deal. It had also "intolerance of light" at this time.

The physician gave a cool bath and a dose of brandy. By the next day the patient had recovered from the serious symptoms, including the diarrhea.

"Recovery was rapid and uneventful."

After this attack of bowel-trouble digestion seemed as well performed as usual. Two months later (*i. e.*, at ten months of age) it was specially noticed that the child could not sit erect. Nothing had seemed abnormal until now, other than undue lassitude. On examination, Dr. J. S. Hackney found that "there was an antero-posterior curvature of the spine," the most prominent point being at about the mid-dorsal region.

Accordingly a plaster jacket was applied. This was cut and removed as often as necessary. There seemed to be some relief from this for the now evidently weak back. The jacket was worn for six weeks.

The little patient has kept up a general good tone since then, the back seeming to have become straight and quite strong again; nor has he had any bowel-complaint since that in his first summer.

The present condition seems to date from thirteen months of age, when the child began to have an oscillatory movement of the left eye and later of the right eye. This nystagmus was always the more noticeable in the left eye. At this time, too his health was good. He seemed somewhat nervous, but did not have any convulsive movements, and never has had any such tendency.

At fourteen months of age he had an attack of bronchitis. In the second week of this illness symptoms of what was said to have been tuberculous meningitis made their appearance. Both bronchial and meningeal symptoms, however, disappeared during the third week. Since then, until now, the child has enjoyed very good health, excepting for extreme nervousness, seemingly lit up anew during the illness stated. He now became easily startled and scared. This timidity has become the more apparent as he grows older. He is at present unusually sensitive. His father says the mental faculties are normal, or at times precocious.

The child did not move about if placed on the floor until two years old. It has only been since January, 1894 (three years and two months old), that he has at all begun to "pull" himself to a standing position with his arms with the aid of a chair, bed, etc. Now, when up, he can walk along the side of the bed or balusters, holding firmly for support. This ability has been acquired only within the past few months. Even when thus holding himself upon his feet he seems in fear of falling. He will, therefore, not attempt to use his feet unless holding firmly to some object.

The patient has been extremely constipated until about a year ago. Since then the bowels have been reasonably regular. This change has probably been brought about by the greater physical exertion of attempted movement.

The child is rather pale; the muscles are fair in size, but very flabby. The head is large, but sym-

metrical. The chest is large, indeed unusually full for a child. He does not crawl, but he can shuffle about, seated; he can walk about when supported, but with a marked ataxic gait and with feebleness. He "kicks" the legs forward in the effort at locomotion. The erectores spinæ are weak. The abdominal muscles and thigh-muscles do not hold the body steadily erect on the legs. He leans too far forward or back. The tendency is more backward, however, when he is thus supported. He cannot feed himself.

Incoördination is marked in the hands, but there is no tremor. He uses the left hand better than the right, and possibly the left leg a little better than the right one.

Nervous system. Sensation is perfect everywhere. Knee-jerks and elbow-jerks are normal, and no ankle-clonus exists. Muscle-jerks of the arms and legs give normal response on stimulation with the percussion-hammer. Electrical examination shows no alteration to faradism or galvanism. The child seems intelligent and alert, though timid and nervous. No signs of pain were elicited at any time during the examinations. He talks fairly, drawls his words somewhat, but speaks freely. The mouth and teeth are normal. There is no preputial adhesion, no incontinence of urine, and this excretion is normal.

Eyes (examined by Dr. A. G. Thompson). The "pupils react normally to light and accommodation. There is no choked disc. The nystagmus of both eyes and the convergent squint of the left eye are, therefore, not due to any refractive error," but are incoördinate movements, such as are seen in other parts of the body.

All other functions and organs are normal.

It seems reasonably clear that the cause of this interesting malady was not prenatal. The child remained well until he had the too common experience of summer diarrhea, followed as we see so often by brain-symptoms. What happened then is not now clearly known. He is said to have had "spurious hydrocephalus," and was, according to the note, very ill. At or after this time he could not sit up as he had been able to do. At the thirteenth month nystagmus began, or was first seen. Then followed a bronchitis and other brain-symptoms described as "tuberculous meningitis," and from this too he got well, and was seen to be more and more awkward as he grew older.

I confess to some puzzle in this case. There are no eye-ground signs. There is no wasting. There is no palsy of any nerve. There is unusual power from crown to sole; there is no sensory loss, and yet he cannot stand at all without some stay. Aided by a finger he can walk, throwing his feet out, and "clumping" precisely like a true spinal ataxic. But no such case in an adult had ever such a degree of disorder without disturbed feeling, or pain, or anesthesia, or girdle-pain, or pupillary signs. Here are none of these. Also, the ataxia is in all the limbs, but is worse in the legs. In the arms and legs, to my surprise, I found normal tendon-jerks, so called, and also normal reinforcements of these muscle-reflexes. There is nothing spastic in these. Sometimes they are excessive, probably from reinforcement due to emotion. There is no clonus; but this is rare in the child under any conditions. If this were a spinal ataxy, with added lateral sclerosis, we should have spastic reflex signals and the usual feebleness apt to be seen in that disorder; also the high ataxic movement of the feet seen in our case would be wanting.

Tabes of all kinds is as a rule progressive. The lad before you continuously improves in the use of his limbs. This is, therefore, neither tabes, nor spastic ataxia, nor is it the picture of hereditary ataxia; neither has he pain-crises, or trophic changes, so that probably the posterior nerve-roots and the gray spinal centers are to be excluded from a share in this disorder.

It seems to me possible that the double brain-diseases he is said to have had, and which left his power of mind and of muscle unimpaired, may have fallen on the cerebellum and left it permanently injured in one of its functions. As against this is the lad's gain in steadiness; but even with most of the cerebellum gone birds have after a year been able to fly. The mechanisms of replacement of function are not as yet clear to us, although we are often called on to recognize their value.

It is then possible that the cerebellum may have suffered over a large area of the surface, and that this damage may have been in part repaired, and a share of the functional activities safe-guarded and replaced by the other mechanisms which contribute to the integrity of equilibration.

I cannot say, however, that I am, even now, entirely sure as to a cerebellar lesion being the true cause of the ataxic state seen in this child, but it cannot be spinal unless the ataxia of childhood should prove to be a very different condition from that of the adult—an ataxia without sensory, ocular, or reflex symptoms. If we had any evidence of tumor of the cerebellum we should be aided in our diagnosis. In it there may be a knee-jerk, but we have not a sign of tumor.

I confess, as I study this case, to increasing difficulty of decision; as one looks at it, the case is to the eye a typical spinal ataxia; examined more nearly, much is lacking to make the perfect picture of that disorder or disease. But almost as much is also wanting to assure us of a cerebellar origin, and one should remember, I repeat, that we have hardly any studies of spinal ataxia in childhood. I reported one, years ago, which came out of Pott's disease, at the age of five, and was seen by me in a woman of forty. It had progressed in leaps, with long

periods of pathological inactivity. Of the earlier symptoms I learned little.

When as thoughtful a man as Gowers admits that the pain, ataxy, or anesthesia may be due to disease either of the cord or of the peripheral nerves, one sees the tangle into which we have gotten our knowledge of the mechanism of harmonious muscle-action, and its offspring, equilibration.

As there may be much loss of motor power, much impairment of motor centers and nerves, without corresponding loss of muscle-harmonies, we must, I think, still look to disease of the nerves of muscular sensation, their spinal tracts, and their cerebellar connection, for the varied seats of the incoordination of complex muscle-acts.

It is conceded that integrity of the knee-jerk, or any tendon-jerk from a blow on the tendon, implies wholeness of the neural arc of conduction and response from the centers concerned. When there is distinct, typical ataxia without spastic states, and with normal presentation of knee-jerk and ankle-jerk, it seems reasonable to conclude that the cause of this ataxy must lie above the region concerned in the muscle-muscle-reactions.[1]

The law which applies to knee-jerks and all tendon-jerks explains *in part* the direct muscle-jerk from a blow. For here, as Morris Lewis and I have shown, this response is due to two contributions, one the intrinsic muscular irritability, and one the addition from the cord. The former continues after nerve-section; the latter is lost, but its loss is only to be proved by the fact that *you can then no longer reinforce the direct muscle-jerk by remote voluntary motion.*

Such is the case late in posterior sclerosis. A blow on the muscle causes a jerk, but reinforcement is no longer possible. The response from tendon-jerk is only a finer, a more delicate, expression, and a larger one, of the same phenomenon. It is increased by tension, and obeys the law of the so-called tendon-jerk. In this boy neither muscle-jerk nor tendon-jerk is gone, nor yet their reinforcement.

The facts as to all this matter of sensory and motor reinforcement, discovered by Lewis and myself, remain as yet almost unnoticed in the text-books, and unused by clinical inquirers.

As regards this boy, I conclude, then, that the cause of his remarkable ataxic state must lie above the seat of response to the tendon-jerks, and does not interfere with the track of reinforcement, which is easily obtainable.

I must leave this case and its consideration without further words. I do not fully understand it, and the frank statement that I do not may have for you some moral value. Under training, with constant little bribes to do this or that until he succeeds, the lad is steadily improving. Even ordinary ataxics may improve by industrious efforts made with closed eyes, and this child has in his favor a normal mind and entirely wholesome nutrition.

An equally interesting case for study is a woman, now in McCormick ward. Dr. Walker will read the notes, which owe much of their interest to Dr. Musser, in whose charge she has been at the Presbyterian Hospital; and to Dr. Pearce, who is responsible for the blood-counts made for Dr. John K. Mitchell's paper on the influence of massage on the blood-count.

I shall presently show you the case. It is another illustration of clinical difficulty in decision. Here again we have an example of ataxia, typical and also extreme, with, save for one notable exception, perfect knee-jerks and elbow-jerks and entire muscle-jerks from a blow, and all reinforcible:

E. I., female, single, fifty years of age, was admitted into the Infirmary for Nervous Diseases, in the service of Dr. S. Weir Mitchell, March 2, 1894. She is intelligent, and gives the following history as to her illness, amplified by the observations at the Presbyterian Hospital and by our notes.

Family history. The woman is of a long-lived ancestry. Her father and mother are living and well at eighty-two and seventy-five years respectively. Three sisters are all healthy. Two brothers have died of scarlet fever and dysentery, and one sister in infancy. There are no neuroses or psychoses among her relatives, and the patient herself had an uneventful childhood as regards maladies, passing through the usual diseases in mild forms.

In 1887 she suffered from the ordinary symptoms of nervous exhaustion; then she became run down, had anorexia, and felt tired most of the day. These symptoms ran the course of many of the cases illy cared for. Then, after an attack of influenza in 1889, she was almost bedridden for a year from what she says was "weakness" only.

After this she was about again for several months, able to walk with a cane, but could not bear much exertion. She was especially weak in the spine and had considerable pain across the lumbar region. The patient also states that at this time she always had better use of the right foot than of the left—the latter was heavy, and seemed to "drag" in walking.

She continued in this way with but little change in the foregoing meager symptomatology until July, 1890, when she went to the Cooper Hospital, Camden, remaining there three months, with little or no improvement. From thence she was taken to the Presbyterian Hospital, Philadelphia, where she stayed in the wards one year. There she was in a highly neurotic condition, and had hysterical outbursts of crying and laughing. The sequelæ of these climaxes (which occurred, as a rule, near the menstrual epochs) were states of lethargy and again of fear, in which temporary hysterical delusions became prominent. The sick women about

[1] Contra-distinguished from skin-muscle-reflexes.

her were often much frightened by her peculiar wandering talk. In a few days she was apt to regain partial control, and would censure herself for acting so foolishly—of which, however, she had only vague remembrances. At this time, too, she seemed able to walk only with the assistance of a nurse, and only for short distances. Her upper extremities were also weak, and she was clumsy. It was, therefore, with difficulty that she fed or assisted in dressing herself. Under rest and tonics there was improvement of the general health, and on leaving the hospital she was able to walk a short distance with the aid of a cane. She was then at home from March to November, 1892, when she was readmitted to the Presbyterian Hospital, where she has been ever since with a multiplicity of symptoms.

Menstruation was normal up to June, 1893. In July, 1893, she had a severe attack of dysentery. The convalescence was slow, and she was left very anemic, the blood-count showing as low as 581,000 red cells on August 1st of that year. On September 1, 1893, the blood-count showed 950,000 red cells with macrocytes, microcytes, etc. On October 18, 1893, the red cells had increased to 1,620,000. The patient's condition seemed now fairly good. Her color had returned in a measure, so that the outlook seemed more encouraging. There was no menstrual flow between June and October, 1893, in which latter month she had a slight show, which recurred again in November, but never since.

By January 1, 1894, there was no material change, save that in the last few days she was decidedly more anemic again, and had headache, dyspnea, weakness, palpitation of the heart on the slightest attempt at exertion, with edema of the ankles coming on late in the afternoon. There was no edema of the face. The skin, too, has become of a lemon-yellow color, and the conjunctivæ of a bluish tint. Her lips are almost colorless.

The apex beat of the heart is in the fifth interspace. No thrill is felt. The shock of the second sound is readily felt in the pulmonary area. The area of cardiac dulness is normal. There is a soft hemic systolic murmur, low in pitch, transmitted into the axilla, accompanying but not obliterating the first sound at the apex. There is also a higher-pitched systolic murmur (probably hemic) heard in the pulmonary area.

Percussion posteriorly on the left side, a little above the spine of the scapula, reveals an almost tympanitic note. This is probably a transmitted note from the dilated stomach found more directly in front. The area of liver-dulness is slightly increased. There is one tender spot on palpation with the finger-tips to the right of the median line, two inches and another two and a half inches above the umbilical line. On January 16th, 1894, the patient had severe pain in the region of this tender spot, with great pallor and increasing weakness, so much so that duodenal ulceration and possibly hemorrhage was thought of. Dr. Musser had the stools carefully examined. No blood was passed, however, and no parasite could be found as a cause of the severe anemia; but this has latterly been proved to be not *pernicious* anemia. The hemoglobin had at this time gone down to 15 per cent., while the red blood-cells only numbered 930,000. There were also poikilocytes, macrocytes, and microcytes in abundance, while macroscopically a drop of blood looked like slightly tinged muddy water.

By February 22, 1894, the patient's skin and mucous membranes had again brightened. Her general condition also became much improved. She was decidedly less nervous, and sat up a short time in a chair each afternoon, but tired easily and could not walk.

On admission to the Infirmary, March 2, 1894, the following notes were made as to her condition: She is a large woman, a brunet, fairly well nourished, weighing 129 pounds. She complains of a feeling of "numbness and tingling" in her hands and feet. She says if she undertakes to hold anything in her hands she must *see* it in order to feel sure that it is there. She can feed herself, but her hands are too clumsy to permit of cutting her food. She cannot dress her hair. She can button her night-dress, but clumsily, and only as far up as she can see the buttons. These defective acts seem to be all due to awkwardness rather than to actual loss of tactile sense, which seems perfect in the hands and fingers. The disorder is mainly a motor ataxia. There is no subjective numbness or tingling anywhere except in the hands and feet. She does not complain of headache. She has pain in the back after any exertion, such as sitting up. We got her up in standing position, when the following was observed: *Station:* She can stand *only* by being supported on either side; she takes a few steps while being thus held, but the movements are markedly ataxic. The left foot is *pushed* forward. The right one is thrown up and out in utter incoördination.

In the sitting position, unsupported, and with eyes closed she does not sway.

Other than the characteristic gait, ataxia of the lower extremities is shown by an inability to bring the heel of either foot in contact with the opposite instep. Ataxia of the upper extremities is shown *even when lying* by inability to bring the fingers of the outstretched hand to the nose with the eyes closed. *Per contra*, the movements of the lower extremities are less incoördinate when she lies supine.

The reflexes, plantar, epigastric, and abdominal, are normal. The knee-jerks are also normal and reinforcible. There is clonus. In this case, too, there is absence of the normal ankle-jerks, as tested by tapping the tendo Achillis, but they can be elicited by reinforcement. The elbow-jerks are normal and reinforcible. The muscle-jerks are everywhere normal and reinforcible.

Sensibility. She distinguishes the two points of the esthesiometer when placed on different fingers, and points out quite accurately the fingers so touched. There seems to be some delay. Tactile sensation on the palmar and dorsal surfaces of both hands is likewise normal. *The thermal sense* is perfect. As to the weight- (or muscle-) sense, on holding the palm of the hand out (the patient being blindfolded), she distinguishes a difference between the following weights, *i. e.*, "the least observable differ-

ence" of Weber's law:[1] The right palm tells one ounce from two ounces only; the left palm tells one-quarter ounce from one-half ounce. Thus there is a difference in muscle-sense between the right and left arms, and the perception is not as acute as it should be. Numbness and tingling sensations are complained of in the hands and feet. No such paresthesia exists in other parts. There is no anesthesia or hyperesthesia, but there is varying analgesia to a deep pin-prick, as follows: The left lower extremity is analgesic from the groin to the metatarso-phalangeal joints; and the right upper extremity from midway between the shoulder and elbow to the metacarpo-phalangeal joints. The condition of analgesia of the upper extremity is variable, however, as twenty-four hours after the first examination sensation to pain seemed almost as acute as upon the opposite side. The right leg and thigh are at times partially analgesic to a pin-prick, but the areas of defect vary greatly from day to day.

Dr. Willits reports the muscular response to faradism everywhere normal.

Drs. de Schweinitz and Thomson made the following eye-report: "Both discs gray, especially in the deeper layers. Arteries too small, veins normal. Pupils normal. Color-fields (red and blue) *typically reversed*. Form-fields contracted."

The reaction-time of the different senses was next investigated. This reaction-time, however, will remain somewhat unsatisfactory until we record a sufficient number of tests upon the normal and abnormal individual to serve as a basis of comparison.[2]

Mr. Lightner Witmer kindly made examinations of this woman for me at the Psychological Laboratory of the University of Pennsylvania, on March 27, 1894, from which the following is abstracted:

First, as regards the motor nervous system, as recorded on the chronoscope, an instrument for recording the rapidity of a motion.

It was found that to pass over a distance of 50 c.m. it took the right hand $\frac{224}{1000}$ of a second (*i. e.*, 224 σ). In the left hand $\frac{241}{1000}$ of a second was required to pass as quickly as possible over the same distance.

A second series of these motor-impulse experiments (made *after* all the reaction-time experiments), were but little lengthened over the first series, thus pointing to the absence of fatigue of any considerable amount.

The normal rate of movement from the experiments of Profs. Fullerton and Cattell varies from between 87 σ to 180 σ for 50 c.m., as recorded on the chronoscope. The woman's movements were therefore slow.

The reaction-time to sound varied from 181 to 343 σ, somewhat longer than the normal, which varies from 120 σ to 170 σ.

The reaction-time for light varied from 160 σ to 350 σ. The normal light-perception is from 160 σ to 200 σ. The reaction-time to electric shock varied from 200 σ to 476 σ, a very marked retardation—and this too while the muscle-response to faradism seemed normal. Here is one of the enigmas appearing in this curious case.

There is thus a general tendency to slowness of perception. The receptive centers have at least become dulled. Is it the incipiency of organic disease? is the question that presents itself.

The patient's general health is fair. All organs seem normal, excepting that the bowels are a little torpid. She has good control over the bladder, and analysis of the urine is negative. Sleep is undisturbed.

The color has returned markedly since January, 1894, the red blood-cells numbering 3,200,000, and not being altered in shape or size. The hemoglobin-estimation is 60 per cent.[1]

The case as you hear it must strike you as peculiar. Reading this story backward, so to speak, the paresis, the anorexia, the type of mental disorder, all point to hysteria. Then we have added a dysentery, which leaves her with such anemic conditions and accompaniments as, for a time, seemed to make the diagnosis of pernicious anemia probable. The history of the development of the remarkable ataxia is not complete, but its presence is to-day her most obvious symptom. Note also the facts of varying analgesia, the typical changes in the color-fields, the equally curious alterations in these, and you have before you a case of hysteria with some very unusual additions.

As you see her walk, with the aid of two nurses, she usually lifts the feet high, and throws them, so to speak, in a disorderly way. With shut eyes, her motions are all worse, as you may perceive when the ataxic hand-movements are thus studied. You would have no doubt, at sight, of hers being a case of typical posterior sclerosis, and now you would have still less doubt if you recall the fact that she cannot tell the difference as between the weight of a penny and that of a silver dollar. The exact facts are better

[1] Weber used the method of "least observable differences" as applied to sensations of pressure and the measurement of lines by the eye, but Fechner expanded it and assumed that all just observable differences are equally great; so that the law is sometimes called "Fechner's law." Expressed in another way, the results depend on (1) strength of stimuli; (2) degree of excitability. If *two* is constant and *one* is then varied, it is found that if the stimulus be doubled, trebled, etc., the sensation only increases as the logarithm of the stimulus (*e. g.*, stimulus 10, 100, and 1000 times, then sensation increases 1, 2, and 3). There is a *lower limit of excitation liminal* intensity and an *upper limit of excitation liminal* intensity. Thus above this no appreciable increase in sensation can be distinguished. This is called the "range of sensibility." Thus, with 10 grams in the hand, we have to add or remove 3.3 grams before a difference in sensation is perceptible. In 100 grams we would have to add or withdraw 33.3 grams.

[2] Professors Fullerton and Cattell published, in 1892, a pamphlet in the Philosophical Series, University of Pennsylvania, on "The Perception of Small Differences, with Especial Reference to the Extent, Force, and Time of Movement." Ten normal persons were examined.

[1] After the administration of ferri pyrophosphas in divided doses up to 95 grains in some 70 hours, the blood-count showed increase of red blood-corpuscles to 4,160,000, and of hemoglobin to 70 per cent.

related in the case-notes. Apparently she has more or less loss of the sense of amount of muscular exertion put forth, loss of muscle-sense.

Naturally, I look with suspicion on a hysterical woman long in hospital-wards, but as to the facts I have stated, I do not think we can have been deceived. I shall presently return to this matter of loss of muscle-sense.

Considering the case as ataxic, such as we see here at every clinic, you would be surprised to find, as I now show you, that we have normal knee-jerks, elbow-jerks, and muscle-jerks, and also normal reinforcements. The responses are not spastic, and the limbs are not like those of people with lateral columnar disease and "lead-pipe" passive flexion. There is no clonus: I can get no ankle-jerk by a blow on the tendo Achillis or on the sole of the foot. I can call out this response by motor or sensory reinforcement. But for this remarkable exception I should have almost no indecision as to how to characterize this deeply interesting case. Perhaps I should not give too much importance to the partial loss of ankle-jerk, especially in a case so profoundly hysterical. Is this case, then, an hysterical ataxia due to hysterical loss of muscle-sense? That this should be, along with preservation of muscle-reflexes, and with no tactile sense, and only variable cutaneous analgesia, is interesting and unusual, and, let me admit, a little puzzling. We may not too readily conclude. Hysteria confuses, but does not exclude organic spinal maladies, and the partial loss of the lowest muscle-reflex is suspicious. But there are no other signals of posterior sclerosis, no pain, no reflex losses in the ataxic arms, no eye-signs. On the whole, I conclude that we have here an unusual type of hysterical disorder of movement.

Briquet, whose pictures of hysteria look to me a little too vivid, described a form of ataxia due to loss of both skin-sense and muscle-sense. He seems to think that the loss of the latter is not to be met with until the former has become positive. With this double loss comes incapacity to effect a motor purpose without seeing the acting member. With view, he says, the muscular acts are perfect. This is not the case in our patient, nor do I think it ever is in these cases precisely as he states it. The sight helps the true hysterical ataxic, but does not enable her to attain ease and perfection in her acts. In the present case there is probably a partial loss of muscle-sense which is hysterical, and very exaggerated motor consequences.

The interest of it lies in the isolated loss, without equal absence of cutaneous tactile sense. I have often seen more or less surface-anesthesia with more or less or no loss of muscle-sense. The great defect of this latter seen in our present case, without any notable tactile loss, is more than merely uncommon. Again, with the ataxia and failure to estimate differences in weights, we have complete muscle-reflexes—all of which make one suspect that the cause of ataxia may lie above the planes of these reflex areas.

In the same ward is a girl of twenty-two, who has the more common form of hysterical ataxia which I described many years ago. She is now nearly well, but a month ago her walk was a thing most interesting to see. She walked as a jointed doll endowed with life might walk, a succession of jerky abruptly-ended movements, with sway of head and body back and front, or to right and left. For a fuller account I refer you to my original delineation of this singular form of disorder.

Our patient was put alone in a room, given very decided faradic currents to the muscles with the wire brush on a dry skin and daily full massage.

She has been rapidly improving. At first, to aid her steps, she used the device I described long ago as crutch-canes, but she can now walk unaided; she has deserted her bed; knits and sews, and altogether seems a gratifying and prosperous case.

April 23, 1894. Her station is good with closed eyes. Sensation is now normal in all forms, and the obvious delay in perception exists no longer. She can now walk some twenty feet unaided. I do not feel at all secure that she will ever be entirely well.

MOOTED POINTS AS TO FRACTURES OF THE ARM, WITH NOTICE OF AN IMPROVED SPLINT.[1]

By J. McFADDEN GASTON, M.D.,
of Atlanta, Ga.

It is my purpose in this paper to ask the attention of the Fellows of the Association to some practical considerations touching the treatment of fractures near the articulations of the arm. There have been divergent views of surgeons as to the management of the osseous lesions in close proximity to the wrist-joint, the elbow-joint, and the shoulder-joint, so that so far as may be practicable, it devolves upon us to arrive at uniformity of practice.

To a considerable portion of the profession it may appear that "old things are passed away, behold all things are become new." But there are still some among us who prove all, and hold fast to that which is good. It is to those who are disposed to judge surgical appliances by their merits, and not by their novelty, that I appeal for a correct decision of these mooted points. I am impressed with the benefits likely to accrue from an interchange of the observations of different surgeons upon this class of fractures, and I trust that those having had expe-

[1] Read before the American Surgical Association at its meeting at Washington, D. C., June 1, 1894.

rience in the management of them may join in the discussion.

It may be promised that, in cases of fracture complicated with dislocation, there is not any good reason for carrying out the injunction of some authorities to set the fracture and splint the bones before proceeding to reduce the dislocation. It is not often that such an adjustment of the fragments of the bone can serve or be made available for leverage or rotation in correcting the dislocation; and whatever may be the appliance, it must necessarily be deranged by the efforts to effect the replacement of the luxated bone. Of course, the readjustment of the dressing will devolve upon the surgeon, after undertaking the reduction of a dislocation under such circumstances, and hence it has to me appeared best to resort to any and every means for reduction before setting the fracture.

The management of dislocations in joints contiguous to fractures must claim careful consideration in treating such cases, and it is encouraging to note the success that has attended the devices for correcting luxations in advance of adjusting the dressing for the fracture.

As this is not entirely germane to the object of this paper, I will not enter into details, but simply insist that in every case of fracture near an articulation complicated by luxation, the correction of the latter should be a preliminary step to treating the fracture. Whether at the wrist-joint, the elbow-joint, or the shoulder-joint, this plan holds good for the observance of the surgeon, and he who fails to adopt it must encounter increased difficulties in securing a satisfactory result. Not only should the luxation be corrected at the outset, but efficient measures should be resorted to for obviating recurrence of the dislocation before proceeding to adjust the broken bone.

Instead of proceeding, as is usual in the description of fractures, from above to the lower part of the arm, I shall consider this plan as more honored in the breach than in the observance, and commence with the wrist, as was done by Gross in his work on *Surgery*.

The only fracture of this portion of the arm in regard to which there is any noteworthy feature of divergence in practice is that of the lower extremity of the radius, known as Colles' fracture. This occurs generally at a distance of from a half to an inch, more or less, from the carpal articular surface, and may be transverse or with an obliquity inward or outward on the part of the lower fragment. It is accompanied with a characteristic deformity of the wrist, corresponding to the shape of a silver fork, and may be complicated by a displacement of the styloid extremity of the ulna. The adjustment may be effected in most cases by extension upon the hand and pressure over the projecting lower fragment, but there is usually much difficulty in maintaining the apposition of the fragments.

It is remarkable that devices so different in their practical operation should have been adopted by surgeons for the correction of this deformity; and the names of authorities in various eras have been associated with splints for Colles' fracture, of great variety in form and application. One considers it best to have a single dorsal splint reaching to the carpal bones; another holds that a palmar splint, having a prominence within the hand, is all that is needed; still another claims that dorsal and palmar splints, extending only to the hand, with appropriate compresses next the respective surfaces, are requisite. But a time-honored appliance, which bears the name of Nélaton, with one or two splints having a pistol-handle curve at the hand, extending from the elbow to the ends of the fingers, has been adopted by some throughout all the changes, and with a satisfactory result. I need not dwell upon the multiform devices introduced at different times by surgeons for this class of cases, as you are all presumed to be familiar with them. But while the conditions to be fulfilled are the same, we must use a wise discretion in selecting that mode of treatment which accomplishes the best results. I realize fully all the difficulties to be met, and recognize the claims made for many of these so-called improvements in dressings for Colles' fracture, yet the ground of the objections to the splints with a pistol-handle curve in these cases is not valid. It is held, for instance, that they do not admit of mobility of the fingers and the carpal bones, and hence that there is increased liability to stiffness of these parts subsequently. If there is any just foundation for the rule in surgery which I have been accustomed to inculcate, that in fractures the immobility of an articulation on the distal side shall be secured in dressing such injuries, then the apparatus for Colles' fracture should control completely any movement of the wrist-joint and the fingers. This is effectually accomplished by the splint originally adopted by Nélaton, and used to a greater or less extent since by surgeons of this country and of other countries throughout the world. If these parts are kept at rest from the very outset of the treatment, without undue constriction, there is decidedly less tendency to inflammation of the structures involved than under the plan of frequent movements of the wrist and fingers, which have been insisted upon by those opposed to the pistol-handle splint. I am convinced that the inconvenience and danger of confining the hand in a state of extreme extension toward the ulnar side have been very much exaggerated, and that its advantages will be realized by all who use the proper precautions in carrying it out.

The dorsal and palmar Nélaton splints, with appropriate padding and compresses, serve to keep the fragments of bone on the outer and inner aspects of the arm in their proper position, and with the extension effected by curvature of the hand from the radial border by the pistol-handle shape all the requirements are met for the prevention of deformity. Those who have adopted other measures without first having tried this should put it to the test of experiment.

I am not urging the claims of the pistol-handle splint upon theoretic grounds, but from practical observation of its advantages in the treatment of Colles' fracture. It seems to have been employed by some with bad results, but I am impressed with the fact that the application of palmar and dorsal splints, which do not press unduly upon any portion of the hand or arm, is not attended with any unfavorable effects. The placing of a splint either anteriorly or posteriorly, which extends only to the wrist and is secured in position by adhesive strips or bandages encircling the arm, is more liable to produce engorgement of the structures of the hand than the uniform support given by a roller-bandage, with splints extending from the ends of the fingers to the elbow. Again, the injunction of the advocates of leaving the fingers exposed, that movements of these and the carpal bones should accompany the treatment, is more likely to increase the local inflammation than a process to maintain complete rest.

Early movement of the fingers and the carpal joint must increase the tendency to subsequent stiffness from the aggravation of the inflammation in the sheaths of the tendons leading to their adhesion. Thus the effect, which we should seek to avert by rest is induced by early passive and active movements. It is undoubtedly true that inaction of a part for a considerable period is followed by inability for a time to accomplish voluntary movements of the structures involved. But if there have been no inflammatory developments, there will be no adhesion of the tissues, and passive motion will soon restore mobility to the parts. After considerable experience with the double pistol-handle splints in the treatment of Colles' fracture I have not observed a single case in which there has remained any permanent impairment of the use of the fingers or of the wrist-joint, nor has any material deformity at the point of fracture followed this treatment. A recent cure confirmed all that is claimed for it.

The next division of fractures to which consideration is asked pertains to the bones above and below the elbow-joint, not leaving out fracture of the olecranon, though this is being treated generally by the same methods as were adopted long ago.

With the exception of the head and neck of the radius, in which fractures rarely occur, there is a great liability to osseous lesions in the vicinity of the elbow-joint, and no class of cases appeals with more urgency to the surgeon for a clear diagnosis and for the adoption of precise measures for treatment.

Dislocation of the head of the radius or the upper part of the ulna is frequently observed in connection with fractures of the lower extremity of the humerus, making grave complications and requiring correction before proceeding to dress the fracture.

The feasibility of adopting any general principle in regard to the relative position of the arm and forearm which shall meet all cases is of paramount importance. A wide diversity in this respect has long existed among surgeons of prominence, and more recently the claimants for the flexed and for the extended position of the arm have contended strenuously for their respective plans of treatment. There may be such a difference in the conditions involved as to warrant the preference for the one or the other mode in special cases, and perhaps some surgeons may secure a satisfactory result in fractures near the elbow with the extended position of the arm, while others may find the flexed position most advantageous. It behooves us, however, to investigate very thoroughly all the bearings of these different modes of dressing the arm, when there is likely to be such inflammatory involvement of the articulation as to induce ankylosis of the elbow-joint. All must know how useless to its owner is a stiff arm in a straight posture, and also how convenient it is to have a stiff arm flexed so as to approach a right angle. While it is held that, with proper precautions in the management of these fractures, ankylosis should not occur, yet there are cases with such complications in which this result will ensue in spite of the best directed treatment. If the surgeon is called upon to treat an injury about the elbow in which he cannot reasonably expect to arrest ankylosis of the joint, there remains no question as to the propriety and even the necessity of employing the apparatus of angular form in dressing the fracture.

But a decision in regard to adopting the straight or angular splint should be made upon a basis of adaptability to the special conditions presented in the case, and while it may be discussed from a theoretic standpoint, the only final solution must depend upon the comparative results of the two processes. The practicability of maintaining the fragments of bone in proper apposition, when the fracture involves the articulation or is in close proximity to it, is promoted rather by the flexed than by the extended position of the arm after proper reduction has been effected.

Should there be a fracture immediately above the condyles, the lower fragment is in my observation prone to project forward, and bringing the forearm

up to a right angle, or even to an acute angle, assists in keeping the fragments in apposition. If the projection of the lower portion of bone be directed backward, and it can be forced into line with the shaft of the humerus by direct pressure accompanying extension, then the flexed position may be adopted with advantage in applying the dressing to maintain apposition. The rather fanciful claim in favor of the extended posture being favorable to preserving the outward angularity of the forearm upon the arm is not entitled to any special consideration, as there is nothing in the flexed position to interfere with this relation of the radius and ulna to the humerus in the restoration of the bony structures.

The comfort and convenience of dressing the arm in a flexed position for fractures near the elbow commends this position strongly in preference to the extended position, and it is to my mind totally inexplicable why a straight splint should be used, except for fractures of the olecranon.

Of course, the utmost care is requisite to detect the exact osseous lesion of either bone, and whether the injury involves the lower portion of the shaft of the humerus, its condyles, epicondyles, and the epitrochlea on the upper border of the articulation, or the upper part of the ulna, with the coronoid process and the neck of the radius on the lower border, there is an urgent demand upon the surgeon for the greatest diligence in restoring the parts to their proper position. The establishment of their normal relations to each other should be the aim of our manipulations, and when this is not practicable we must count upon more or less deformity as a consequence. Without disregarding the apprehensions of authorities as to the dangers of constricting the limb unduly by a bandage, I find a roller applied from the fingers along the forearm and extending above the seat of injury to be advantageous, having the arm flexed at the elbow to a right angle. This angularity calls for support of like form, and taking the sound arm as a model, the outline is marked out upon large thick pieces of pasteboard, so as to extend from the wrist to the shoulder, corresponding to the outer and inner aspects of the limb. The board is cut so as to meet on the anterior and posterior median lines, is then soaked in water and molded accurately over a thin layer of cotton-batting around the entire member. If the edges are notched at a single point in front of the joint and at two points behind the joint the adaptation to the curve of the elbow will be more satisfactory. Should the sheets of pasteboard be light, several layers may be put together and held in place by a roller bandage before applying them. They are secured by a bandage passed from below upward, while an assistant turns in the margins to be molded with only sufficient force to afford proper support to the structures about the elbow. After completing this application a dry, strong, angular pasteboard splint, or one of pine board should be bound to the inner side of the arm until the moistened pasteboard mold shall dry and become firm.

This mode of dressing has all the advantages of the plaster-of-Paris in its accurate adaptation to the parts and its efficient support, while it can be removed and reapplied daily if requisite.

The results obtained by this mode of dressing fractures near the elbow in young subjects have proved entirely satisfactory, not being followed in any case by ankylosis or permanent impairment of the movements at the joint. A comparatively small number of adults have been treated by this method, yet these have progressed favorably in every respect, and recovered full and free action of the arm.

Three months ago I had occasion to treat a laboring man, who sustained a fracture of the internal condyle, with a backward dislocation of the ulna, which was followed by extensive general inflammation about the joint and forearm. After reduction of the dislocation and coaptation of the bone, pasteboard was fashioned from the sound arm into angular splints, and after being moistened was molded to the palmar and dorsal surfaces of the injured arm, and placed at a right angle, with the thumb protruding in a directly vertical position between the splints.

The splints extended from the shoulder to the tips of the fingers, over layers of cotton-batting adjusted to the irregularities of the limb, and secured throughout the entire length by a roller-bandage. The forearm was then suspended in a sling around the neck, with the injunction to keep the arm at rest. Upon removing the dressing at the end of a week there was considerable ecchymosis, with swelling about the elbow, and friction with a liniment of spirit of turpentine and olive-oil, each two ounces, and pulverized camphor two drams, was practised freely before reapplying the firmly molded outer and inner splints with the roller to support them. The dressing, with the friction, was renewed every three or four days, without attempting any movement at the elbow for a month. Afterward passive motion of the joint was cautiously practised at each dressing, and gradual improvement has been observed, but there is still impaired mobility of the elbow. There is, however, no ankylosis, and I feel assured that, with use of the arm, which the man is now making in his daily work, the normal movements will be completely restored at the elbow-joint. I doubt very much whether such a favorable result could have been effected by treating this case with the arm in the extended position.

It is claimed by the advocates of extension of the arm in the early treatment of fractures near the elbow-joint, that in cases liable to become anky-

losed the limb should be gradually brought into the angular position. But this necessitates the very movement of the articulation that will aggravate the inflammation, and increase the tendency to ankylosis. On the contrary, if the arm is originally put in an angular position, affording the greatest utility to the member, it can be kept at rest in that position until all inflammation has disappeared.

The last questionable point to which reference will be made is that touching fractures near the head of the humerus. These may be intracapsular, involving the head and the anatomic neck, or they may only implicate the tubercles outside of the capsule. The most frequent seat of fracture, however, is through the surgical neck, which extends from the line of epiphyseal union to the attachment of the latissimus dorsi and pectoralis major muscles. The lines of fracture in those portions of the upper end of the humerus may be in various directions, and being covered with the thick structure of the deltoid muscle, the differential diagnosis is attended with great difficulty.

But, fortunately, the verification of fracture in any direction of this part of the bone will suffice for the adoption of measures suited to the case, and it is for this class of fracture that I have devised and adopted a special splint. The object being to effect extension and counter-extension, so as to keep the fragments in their proper relations to each other and at rest, this splint is well adapted to fractures of the shaft of the bone.

There is a description of this splint in my report upon "Fractures of the Arm," published in the *Transactions of the Medical Association of Georgia* for the year 1887. The case was considered appropriate for a splint having the effect of extension and counter-extension, with complete immobility of the fragments of the bone. It is formed with a right angle in the plane of the boards at the elbow, the upper branch extending into the axilla with a crutch-like termination, and the lower branch reaching the wrist, so that when fitted to the inner face of the limb, and secured by a bandage, with a light board splint molded to the outer aspect of the arm over the fracture, all the conditions are met for retaining the fragments accurately in apposition. It is requisite that the arm shall be kept close to the body by a handkerchief or a piece of cloth, in a triangular shape, passing under the elbow and forearm, and around the neck, so as to be supported. Angular splints, extending from the wrist to the axillary space have been employed by others, but the crutch-shape above is the special feature of the splint.

The same principle of extension for fractures of the humerus was presented many years ago in an apparatus of Lonsdale and in appliances of S. W. Hind, so that I do not lay any claim to priority, though unacquainted with their devices when my plan of treatment was originally adopted. The plan adopted by them was to attach a crutch-shaped piece of metal to the brachial limb of the splint, which was operated by a screw and cogs to adjust it to the length of the arm in different cases.

The wooden splint is measured by the sound arm, with the crutch projecting beyond the axillary folds, so as to have firm resistance when the lower branch is bound to the forearm of the affected limb. An opening is made at the angle, so as to avoid pressure upon the internal projection of bone at the elbow. The brachial face of the splint is padded with cotton-batting, and the concavity of the crutch is also well padded, while the cotton is secured by turns of a roller-bandage. When this splint is accurately fitted to the individual case it meets all the indications for fractures of the upper extremity of the humerus in a most efficient manner.

A fracture of the surgical neck of the humerus extending to the tubercles has recently been treated with this angular crutch-shaped internal splint, in the person of a white man of forty-five years of age, by my son, Dr. J. McF. Gaston, Jr. It was suspected at the outset to be complicated by a luxation of the head of the humerus, but an examination under the influence of an anesthetic eliminated this doubt in regard to the nature of the injury, and the diagnosis of fracture was confirmed by the evidence of crepitation. There was considerable inflammation about the shoulder, as three days had elapsed since the reception of the injury, and the slightest movement was attended with great pain, so that the anesthesia was essential for obtaining the information requisite for a correct view of the case. A medical attendant had at the outset entirely ignored the nature of the injury, and entered upon a course of treatment under the supposition that it was only a severe contusion of the part from a fall on the shoulder.

The angular splint with the axillary crutch, and the lower branch extending to the fingers, was excavated at the angle to accommodate the internal epitrochlea, and being properly padded, was ready for adaptation to the inner aspect of the left arm. A roller-bandage, applied from the fingers to the shoulder, to obviate the irregular contractions of the muscles and to prevent the extension of swelling to the forearm, should have preceded any other dressing, but was omitted in this case, in compliance with the practice of some high authorities on the treatment of fractures. With a layer of cotton-batting enveloping the entire arm, the crutch-extremity of the angular splint was pressed up firmly against the axillary fold, and the forearm held by an assistant in contact with the lower branch of the splint, while a roller-bandage was carried around the limb from the hand upward, securing also an outer splint molded to the humerus and the shoulder.

Thus support, with extension and counter-extension, was effected. The lower transverse branch of the splint, having the forearm firmly fixed to it by the bandage, kept up the extension, while the crutch-shaped portion pressing against the axillary fold maintained the counter-extension. It will be understood that the addition of the outer splint molded to the shoulder and supported by the bandage fulfilled all the conditions for securing the proper coaptation of the fragments of bone at the surgical neck of the humerus. The patient was provided with a sling, passing under the forearm and around the neck, so as to support the limb when in the erect posture, and expressed himself as being more comfortable than at any time since receiving the injury.

Upon redressing the arm, after the lapse of several days, it was found that there was a tendency to swelling of the hand and forearm, whereupon the roller-bandage was applied directly to the limb, and was kept up afterward with good effect.

After the lapse of six weeks the angular crutch-shaped splint was dispensed with, and the bony union was firm, but with exuberant callus there was considerable enlargement of the upper extremity of the humerus and inability to accomplish upward movements of the arm. Passive motion, backward and forward, could be made with facility, and by continued use of the liniment of camphorated oil and spirit of turpentine about the shoulder the upward movements have so improved that after nearly four months the man is able to use the left arm in the performance of most of his duties as a carpenter. The callus has been so far absorbed as not to leave any deformity, and the prospect is very favorable for complete restoration of the functions of the arm within a brief period.

It may not appear that the results in these special cases are conclusive, but, with an experience of many years favorable to these modes of dressing the respective injuries of the arm, I feel warranted in commending them to the confidence of the profession.

GYNECOLOGY AMONG THE INSANE, FROM THE GYNECOLOGIST'S POINT OF VIEW.[1]

BY W. P. MANTON, M.D.,
OF DETROIT, MICH.,
CONSULTING GYNECOLOGIST TO THE EASTERN AND NORTHERN ASYLUMS FOR THE INSANE, AND ST. JOSEPH'S RETREAT; GYNECOLOGIST TO HARPER HOSPITAL, ETC.

BUT a few decades have passed since the mentally alienated were looked upon as outcasts, possessed of devils, witchcraft, and altogether inhuman. The necessary protection of society from such monsters in human form led to their incarceration in prisons, where they passed their lives in misery, in many instances chained to floor or pillar, unkempt, half-naked, and wallowing in their own filth.

[1] Read before the Michigan State Medical Society, May 4, 1894.

As the increasing number of this unfortunate class made other accommodations necessary, asylums were erected for their reception, but the prison-system still continued, until in the natural evolution, of knowledge, men began to understand that mental derangement was *not* crime but disease, and humanity demanded a more rational and kindly treatment for its kith and kin.

Until quite recently, however, the housing, clothing, and feeding of the insane was considered all that could be done or was necessary for these unfortunates. But increasing experience soon taught that this was not sufficient; that if the mentally sick were to recover, if they were ever again to assume their places in society as responsible men and women, other means besides the supplying of their animal wants must be brought to bear upon their condition.

And so to-day, in the leading institutions of this country and abroad we no longer find bare walls and desolate halls filled with the unemployed, but rooms made bright and cheerful with pictures, flowers, and birds; and hygiene, work, and amusements have become important factors in the treatment of insanity. In other words, mental derangement being now regarded as a brain-*sickness*, the asylum has assumed the functions of the hospital, and the prison-idea has been relegated to oblivion. But even the progress that has been made during the past few years is not at an end, for the good work so well inaugurated must still go forward, and the various *ailments* that afflict the body must be investigated and relieved. It is along this line, as surely as in the study of mental pathology and symptomatology, that advance in the future is to be made, and I here prophesy that the time is not far distant when no patient will be dismissed from the asylum as mentally cured until all morbid somatic conditions from which he may be suffering have also been relieved, or, if incurable, ameliorated as much as is possible.

I am here to-day to reiterate what I have so often said and written, that the insane, even the hopelessly demented, have as great a right to relief from all somatic ailments as those whose mental integrity has rendered asylum-hospital treatment unnecessary.

That insane women are as capable, in most instances, of suffering as acutely from local disorders as the sane has been demonstrated time and again, and that these affections often have a greater or less influence on their mental condition is now too well known to require comment. A careful perusal of the reports of our leading asylums will convince even the most skeptical that these are not theories but facts. The question so often brought forward is: Will the relief of these conditions restore the patient to mental soundness? I maintain that this

view of the subject is both wrong and inhumane, and that the query should be: Will it do the patient good, relieve bodily suffering, and perhaps in this way ameliorate the mental symptoms manifested? Not every sane woman suffers from uterine or appendiceal disease, nor does every insane woman so suffer, although I am inclined to think that the proportion is slightly greater in the latter class than in the former, but in any community of several hundred souls there will be found some that are thus afflicted.

In the majority of asylum-cases the patients are quite capable of describing the nature of their sufferings, and to ask for help; but in a few the mental state may be such as to prevent this. In such instances, the watchfulness of the trained attendant detects by the manner, the expression of countenance, and general attitude of the patient that something is wrong and demands investigation. Such appeals from the helpless wards of the State should not be neglected, and I am happy to say that, in Michigan asylums at least, they are never disregarded.

In regard to the local treatment of the insane, I may say that in my experience it has given very satisfactory results, and I can see no difference between the sane and the insane in this respect. In a number of instances I have performed various minor operations upon asylum-patients, such as the restoration of the lacerated cervix and perineum, the removal of the carcinomatous breast, etc. Such operations do well as a rule in the insane, and, by the relief of the peripheral irritation, have a more or less decided influence upon the mental symptoms of the patient.

Perhaps, however, the greatest interest in this whole question centers around abdominal surgery in the insane. In a recent paper on this subject[1] a number of cases of celiotomy, embracing such conditions as fibroids of the uterus, ovarian cysts, ventral hernia, and chronic appendiceal disease, upon which I had operated were considered in detail, and to this paper those who are especially interested in the subject are referred.

There can be no doubt that surgical procedure for the relief of suffering, when gross pathologic changes have taken place in organs or parts, is generally quite justifiable. My results from the removal of new growths, etc., have been eminently satisfactory, and in all but one case recovery from the operation has been rapid and uneventful, and in nearly all instances have the patients improved mentally. Indeed, so frequently have the mental manifestations undergone a decided change for the better that I have now come to look for this almost as certainly as for recovery from the operation.

[1] The Physician and Surgeon, May, 1894.

In discussing this question, however, we must guard against taking too optimistic a view of the subject, for, in all my experience, I have never yet seen a patient entirely relieved of her mental disorder as the result of operative treatment. In a few of my cases the marked mental improvement following the operation has given rise to the hope that an ultimate cure of the brain-sickness might result, but other conditions being present, over which neither medicine nor surgery can prevail, have led to disappointment.

To the castration of women for the cure of insanity I am utterly opposed, and I believe that the operative furor which is now so prevalent in this country has led to many unnecessary and unjustifiable mutilations of these helpless women, which otherwise would not have been tolerated. Such procedure, in my estimation, is not only to be deprecated but also denounced, and the abdominal surgeon who undertakes to cure mental alienation by this means brings discredit not only upon himself, but upon the specialty that he represents.

In the hystero-neuroses, when the symptoms point to the tubes or ovaries as the source of irritation, the removal of the healthy adnexa is at times quite warrantable, and the end often justifies the means. In insanity, however, the pathologic changes in the cord and brain upon which the condition depends should indicate to even the most superficial observer that ablation of the normal appendages can have no curative effect.

In summing up my conclusions, based on many years' experience in the practice of gynecology among the insane, I have no hesitancy in presenting the following:

1. That insane women have both a moral and a legal right to amelioration from suffering dependent upon local disorders, without reference to the effect that such relief may have upon their mental condition—that is, as regards cure.

2. That indiscriminate operating upon the insane, especially the removal of the normal appendages for the so-called cure of insanity, is not only to be deprecated on account of its utter uselessness, but also denounced because of the unnecessary mutilation of the patient.

32 ADAMS AVE., W.

STUDENT VERSUS MEDICAL SCHOOL.

BY BAYARD HOLMES, M.D.,
PROFESSOR OF SURGICAL PATHOLOGY AND BACTERIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO.

IN an article by Dr. Allis in THE MEDICAL NEWS of June 16, p. 661, medical schools are charged with farcical entrance-examinations, with unusual and burdensome courses of study, with cramming and quizzing for hospital-appointments,

with exacting examinations, and with plucking a large percentage of students under any circumstance.

Are these charges to be sustained?

It is a fact that all applicants are received in most medical schools and that the entrance-examinations are farcical, except in the State of New York, where they are puerile. There are individual exceptions to this rule, probably to the number of ten medical colleges, or, say, one-tenth of the total number of schools.

Is the course of study burdensome in its extent? Certainly our present courses, as laid out in the announcements of 1893–94, are still very far from equivalent to four years' work in any other department of the university. The method of teaching, which is a natural consequence of its motive, is bad, in every way bad, from a pedagogic standpoint. In this, of all professional schools, the true relation of physiology and psychology to the course of study and to the order and quantity of work should be exemplified. But nothing of the kind is the case. No medical school, so far as I know, makes any serious attempt to teach experimental psychology. In no one are the courses arranged with a pedagogic regard for sequence, and in no one does that first law of teaching, "The concrete before the abstract," receive the least recognition. If the student is overcome with much work and with too many studies and too many examinations, it is because the year is not properly divided into three or four terms of three or two months each, and the many subjects of the year equally divided into portions, one for each term, with final examinations at the end of the term; or, again, it is because the subjects are presented to the students in an unscientific and unschoolmasterly way, so that the students are not educated but crammed. In any case it is not because the medical schools attempt too much, but because they attempt to use the methods of our ancestors.

Let us admit that in law-schools a better method has been introduced, the case-system, and that in theology more careful and thorough methods have long been used. Let us admit that the schools of medicine attempt to teach in classes entirely too large for efficient instruction. Nevertheless, the fact remains that the course of study is not more extensive than the welfare of future patients demands. In regard to the number who are annually "plucked" at the final examinations not much can be said. If all were graduated, there would be another crime added to those already committed. The absurd custom of graduating all together at only one time in the year, with sound of trumpets and with display of flowers and wine, is in bad taste and is unscholarly and undignified. There ought to be at least four equidistant days in the year for awarding diplomas, and then only on the completion of all the work of the course. It is a physiologic absurdity to make an ironclad course of study, an ironclad classification of students into four classes, and then graduate them on a single day after passing an ironclad examination. The educator would devise a system that would allow a strong student to do more work than a weak one. He would not have more than thirty men in any one class under any teacher at the same time. He would not allow a man to take more than four recitation-hours of work a day. He would humanely vary the exercises of any one student and guide him in the selections of his studies.

The educator would tear out the absurd amphitheaters in our medical colleges. He would increase the number of professors in every branch. He would separate the examining department entirely from the teaching department and have one man at its head. He would make the course of study flexible and constituted of an obligatory portion and an elective portion. He would limit the duration of any one course to three months, and he would require at least two examinations during each course. He would have libraries in each and every department, in each and every laboratory. He would see to it that each teacher knew the men he taught and examined.

In relation to the law that recognizes the medical schools and their diplomas, Dr. Allis' points are well taken. The State gives the education of physicians into the hands of physicians and virtually says: "Do this as you please; make what you can out of it. We will let no one practise whom you do not graduate. We will take care of, educate and support the blind that result from the careless and untrained men you send out and of the deaf-mutes that follow the epidemics you treat, all at a cost of $2,855,694 (1890), but we will not give a cent to medical education or to the supervision of medical schools. We have $750,000 a year to invest in the study of diseases of swine; our schools of theology have been liberally endowed by pious citizens ($28,000,000), and our State universities have liberal provision for the study of the Semitic languages, the problems of mining, engineering, and architecture; but not a dollar for the study of the diseases of men." Hogs are of more account to these United States, in the opinion of legislators, than are healthy men. There is no lobby in our halls of legislation from the coming generations, and their parents are too busy with the affairs of to-day to protest against the unfair discrimination against the baby and in favor of the pig. And still the production of defectives goes on. For example: in 1850, in each million 422 were blind: in 1860, 403; in 1870, 527; in 1880, 976; in 1890, 805. The production of other defectives is in about the same proportion. The State, county, and city support hospitals and deny

their use to the medical schools and medical students who will soon be licensed physicians. It would pay the State, even if it were not its duty as the only capable corporation and the one most interested, to support, direct, and conduct all the medical education of the country. This will be done so soon as we, as a nation, value men above all other products of our clime, so soon as men believe that the Kingdom of Heaven may come here in this world as the *Pater Noster* indicates, so soon as selfish men cease to exploit for their own aggrandizement the sacred labor of medical education, so soon as our universities apply the same ethical and pedagogic principles to their medical departments as they use in directing their other graduate schools.

CLINICAL MEMORANDA.

THE DANGERS OF COCAIN.

BY ROBERT W. HAYNES, M.D.,
OF LOS ANGELES, CAL.

THE medical literature of the past year abounds in recommendations of the use of cocain in all sorts of disease, from nasal catarrh to melancholia, and with little reference to the likelihood of the formation of the habit.

One eminent authority and teacher goes so far as to say: "The moderate daily use of coca, according to our best information, is not injurious and increases the working powers;" again he says: "It will probably come into use to sustain men under severe exertion."

The same gentleman refers to cocain hydrochlorate as being useful in one-grain doses as a stimulant to soldiers undergoing forced marches.

Dr. Hammond says: "We have heard a good deal of the cocain-habit—a habit that I am very sure has no existence as such—there is no weakening of the will-power, and there is not as much trouble in ceasing its use as giving up tea or coffee."

As a slight protest against what appears to be a grave error in the estimation of the harmlessness of this terribly seductive drug, the following cases that came under my personal notice are related:

CASE I.—N. E. W., a physician and an opium-eater for years, though absolutely free from symptoms of poisoning, commenced with cocain, gr. ss, hypodermatically to see what effect it would produce. Flushing of the face, dilatation of the pupil and general stimulation ensued. On the following night gr. j hypodermatically was necessary to produce the delightful *bienfaisance* that far exceeded that produced by opium, a feeling of not having a care in the world; of peculiar physical and mental beatitude. The dose was gradually increased until 5 and 10 grains in the twenty-four hours were taken. The irresistible desire for frequent repetitions of the dose was present, as the euphoric stage, though present until the end, grew shorter. The usual neurasthenic symptoms soon appeared, with delusions of persecution and hallucinations of sight and hearing, bright discs of light appearing on the walls throughout the sleepless nights. Loss of memory, muscular incoördination and aphasia followed.

Twice during the existence of the habit over-doses were taken that caused alarming dyspnea, a hardly perceptible and thready radial pulse, extreme mydriasis, pinched skin and drenching perspiration, accompanied by loss of muscular power. These symptoms, in common with those produced by a debauch, were soon relieved by his ordinary dose of two grains of morphin.

This man abruptly abstained from the use of cocain, at three different times, for the space of several months, and has not used the drug for the last nine months.

CASE II.—H. R. N., a druggist, commenced the use of a 4 per cent. solution of cocain as a nasal spray to deplete the erectile tissue, and gradually increased the amount until seven grains were used at a single sitting. Loss of appetite, sleeplessness, headache, constipation, and loss of flesh followed. Muscular incoördination, hebetude, and enuresis then appeared; the last was almost immediately checked by the use of paregoric. Realizing the danger of the habit, the use of the drug was discontinued.

CASE III.—S. E., a physician, first used a 4 per cent. spray of cocain to relieve chronic rhinitis, but continued its use for the stimulation it produced. Finding the effect on the mind very deleterious, as manifested by mental incoördination, he discontinued the practice, but is of the opinion that for many weeks afterward his mental powers were weakened.

CASE IV.—X., a child, two and one-half years old, received at the hands of an experienced surgeon, a urethral injection of gr. ss of cocain, to facilitate the passage of a sound. In a few minutes clonic convulsions with wandering delirium set in, with the usual train of symptoms of acute poisoning, which terminated fatally in three days.

CASE V.—As this is written, news comes from Arizona of the death of a friend at the hands of a dentist, by the injection of four grains of cocain into the gums prior to the extraction of teeth. The patient died in convulsions in an hour, from probably the medicament entering the circulation immediately, and expending its full force on the heart.

Senor Montagessa, after taking cocain, said that God was unjust, in that he had made man to live without eating coca, and that he preferred a life of ten years of coca than one of a thousand without it.

It was my habit in the treatment of nasal troubles to order the use of cocain as a nasal spray, but I have practically abandoned the practice, save in operations, as alarming symptoms, such as dyspnea, apnea, and loss of muscular power, were produced by very small quantities of a 4 per cent. solution.

The cases reported tend to show that the cocain-habit, though abandoned much more readily than the morphin-habit, is acquired with much greater facility and insidiousness; that the remedy for cocain-*poisoning*, as in cases IV and V, is probably full doses of morphin, as indicated by its happy effect in cases I and II.

Erlenmeyer is probably correct in saying that to try to cure the morphin-habit by cocain is casting out Satan by Beelzebub.

623 SOUTH HILL STREET.

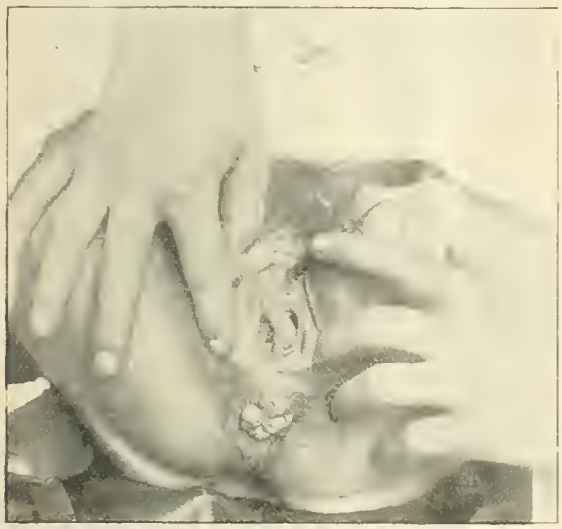
Dr. Percy F. Frankland has been appointed to the Chair of Chemistry and Metallurgy in Mason College, Birmingham, Eng.

A CASE OF DOUBLE VAGINA.

BY CLINTON B. HERRICK, M.D.,
OF TROY, N. Y.,
SURGEON TO THE TROY HOSPITAL, THE COUNTY HOSPITAL, AND THE HOUSE OF THE GOOD SHEPHERD.

A CASE of double vagina recently presented itself to me, and seems sufficiently interesting to record. It is of interest only as an anomaly, as the patient presented herself to obtain relief from hemorrhoids, which were well marked and occasioned considerable distress. Externally, the genitalia were normal. Upon separating the labia, the condition shown in the accompanying photograph was disclosed. The unnatural septum was

FIG. 1.



continuous between the two rather short vaginæ, into each of which there projected a diminutive cervix, but only in the right could an os, continuous with the cavity of the uterus, be found. In the left vagina there was a

FIG. 2.

dimple having the appearance of an os, but into which the probe could not be made to enter. The uterus was diminutive; the other organs were normal. The woman was thirty-five years of age, had menstruated quite regularly, and, though married, had never been pregnant. The diagram delineates the relation of the parts internally.

MEDICAL PROGRESS.

The Treatment of Gangrenous Hernia.—CHAPUT (*Archives générales de Médecine*, May, 1894, p. 523) considers the treatment of gangrenous hernia one of the most complex problems in surgical therapeutics. The prognosis is always grave; whatever the treatment employed there will at all times be an inevitable mortality as a result of generalized infection. Intestinal suture is to be preferred to an artificial anus for a number of reasons. Suture does not expose the patient to the dangers and discomforts of the local condition, and not to the risk of inanition; it affords relief at a single sitting, while the other operation leaves a disgusting infirmity, ultimately necessitating multiple and grave operations. The mortality of the operation for the establishment of an artificial anus is about 28 per cent., and there is no ground to hope that this will be reduced by any technique. The mortality of intestinal suture is from 15 to 20 per cent., and there is ground for believing that these figures will be reduced. The total mortality following the establishment of an artificial anus reaches 80 or 90 per cent., while that from suture is not more than 30 or 40 per cent. The principal improvements in the operation of suture consist in free incision of the constricting tissues from within outward, a sufficient resection of the intestine, including all diseased or suspicious tissues, the employment of an interrupted circular suture, the non-reduction of the loop of intestine, and drainage of the peritoneum. Suture is contra-indicated in case of collapse, of grave peritonitis, or when for other reasons the conditions of operation are not favorable. If the lesions are not extensive it is best to invaginate them and introduce a double row of sutures. If the lesions are extensive, but do not involve the entire circumference of the bowel, one may, if the adjacent tissues are healthy, make a lozenge-shaped excision and unite the free margins as in applying an interrupted circular suture.

Progressive Dementia and Incoordination of Movement in all Extremities in Brother and Sister.—BOUCHARD (*Rev. Neurol.*, 1894, No. 1, p. 2; *Gaz. hebdom. de Méd. et de Chir.*, 1894, No. 28, p. 201) has reported the case of a male child, eight years old, that for three years had presented mental weakness, tremor, and difficulty in walking. The gait was like that of one with cerebellar ataxy; the movements of the upper extremities were also incoordinate. The reflexes were preserved and sensibility was intact. Speech was scanning and the mental processes were apathetic. In the course of a year the feet assumed a position of equino-varus and the child was incapacitated from walking. A year later the mental weakness was pronounced, the extremities had become rigid and could not be moved, and bedsores had formed. Finally epileptiform attacks set in and death ensued. At the post-mortem examination the pia mater was found adherent, but no abnormality of the brain was detected. The spinal cord presented a non-systemic sclerosis of the lateral columns and degeneration of the cells of the anterior horns. A sister of this patient at the age of ten years had for three years shown similar arrest of mental development, ataxic gait, and motor incoördination in the upper extremities, walking ultimately becoming impossible. An attack of influenza terminated fatally and

after death sclerosis of the lateral columns of the spinal cord was found. The father and mother of the patients were well, and three other children of a total of eight were living and well. The paternal grandfather had died in the sequence of an apoplectic seizure; the maternal grandfather had been an inebriate. It is believed that the cases belong to an undescribed form of family affection.

The Relationship between Myxedema and Exophthalmic Goiter.—At a meeting of the Société de Liége, held a short time ago, Canter (*Annales de la Soc. Méd.-Chir. de Liége*, January, 1894, No. 1, p. 12; *Rev. Int. de Bibliog. med., phar. et veterin.*, 1894, No. 8, 133) presented a case of myxedema in a woman, forty-two years old, successfully treated by the administration of thyroid gland of the sheep in doses of a quarter or half a gland or more daily. The treatment was attended with nausea, vomiting, and weakness, when large doses were employed, but more remarkable was the fact that the frequency of action of the heart increased from 76 to 126, while palpitation became apparent; there was also sleeplessness, tremulousness, and profuse perspiration. The opinion is expressed that the symptoms of exophthalmic goiter are due to an intoxication of gastro-intestinal origin, as a result of which the secretion of the thyroid gland is increased, with the development of the characteristic symptoms of the disease, just as they occur after the therapeutic administration of the gland. It has further been observed that the administration of thyroid gland in cases of exophthalmic goiter is attended with an aggravation of the symptoms. In the course of time the thyroid gland undergoes degeneration or atrophy, as is the case with all glands that are subjected to morbid hyperactivity.

THERAPEUTIC NOTES.

Anilin Colors in the Treatment of Carcinoma.—Mosetig-Moorhof (*Wiener medizin. Presse*, 1894, No. 20, p. 761) has reported the case of a woman, fifty-two years old, who presented below the right costal arch a tumor almost as large as a fist. For a period of nine years there had been recurrent attacks of colic of several days' duration and associated with a moderate degree of icterus. The woman was greatly emaciated, of pale-yellow complexion and flabby musculature, and the conjunctivæ were of sub-icteric hue. Upon palpation, the tumefaction was found to present a smooth, convex surface and a firm, elastic consistence, and to be only movable laterally with the abdominal parietes. The dulness on percussion merged with that of the liver. Laterally and inferiorly the tumor could be followed into the abdominal cavity; its fundus was not displaced by the respiratory movements. A diagnosis of tumor of the gall-bladder was made and an operation undertaken. Upon opening the gall-bladder some pultaceous matter was evacuated and the introduced finger came in contact with a soft, friable, yellowish new-growth, arising from the wall of the bladder and occupying the entire cavity of the viscus. By means of the finger and a spoon this growth was broken up and removed, and a small calculus was also dislodged. Histologic examination showed the neoplasm to be a villous carcinoma. The cavity was packed with gauze. On the sixth day the tampon was removed and bile made its way out of the wound. The discharge continued for three weeks, until the opening became much reduced in size and finally closed. Every two, three, or four days a small rod of methyl-violet was introduced into the cavity and nine grains of methylene-blue were administered by the mouth daily. With this treatment the woman improved decidedly, gaining in weight and strength, sleeping better, having an improved appetite, and being free from pain.

Potassium Permanganate as an Antidote to Cyanid-poisoning.—Prompted by the thought that in the treatment of acute and rapidly occurring intoxications the best results are to be expected from chemic rather than physiologic antidotes, Kossa (*Centralblatt für die medicin. Wissenschaften*, 1894, No. 17, p. 289) undertook an investigation into the antidotal power of potassum permanganate in case of cyanid-poisoning. He believed that by the administration of the permanganate the ingested cyanid would be converted into a relatively innocuous cyanate. Experiments with dogs showed that animals to which were administered toxic doses of potassium cyanid could be saved by the immediate administration of potassium permanganate; in one instance even a dose ten times the lethal one failed under these conditions to induce toxic effects. An animal that received a dose twenty times as large as the lethal dose and afterward potassium permanganate lived for a longer period of time than one given an ordinary lethal dose alone. If toxic doses of the cyanid were admixed with potassium permanganate, and the mixture permitted to stand for a few hours, no bad results followed its administration. The investigation points to the conversion of the cyanid under the influence of the permanganate into a hydrocarbonate, then into a carbonate, and finally into urea.

Methyl-violet in the Treatment of Diphtheric Conjunctivitis.—Hilbert (*Memorabilien*, xxxviii, 3, 138) has reported a case of diphtheric conjunctivitis successfully treated by the application with a brush thrice daily of a 3 per cent. aqueous solution of methyl-violet, in conjunction with warm fermentations. Subsequently, instillations of a solution of duboisin sulphate were practised, and the conjuctival sacs were frequently irrigated with tepid, sterilized water.

BERI-BERI.

ALTHOUGH the disease beri-beri is but rarely observed in this part of the world, a more than scientific interest is to be attached to it, inasmuch as sporadic cases are occasionally brought to our seaport towns from infected localities, and the possibility, under favorable circumstances, of extension is not to be ignored. A *résumé* of the more essential features of the affection may therefore be not entirely without utility, and a recent monograph[1] by one who has availed himself of the opportunity afforded by a long residence in Japan for a practical study of beri-beri, will be utilized as the basis of these remarks.

The etymology of the word beri-beri is obscure, although its source is believed to have reference to the impairment of gait, which is a noticeable feature in most, if not in all, cases. The first European description of the disease dates back to the middle of the seventeenth century, and was based upon observations made in the Malayan Archipelago, although descriptions of the disease, under the name of kakké, had been given in Chinese and Japanese writings of a much earlier date. The geographic distribution of the disease includes a large portion of the tropical and subtropical countries of the two hemispheres, although the main seat of the disease is formed by the islands of the Malayan Archipelago, and particularly Sumatra, where the disease prevails both endemically and epidemically. It is also encountered in India, China, Japan, Africa, and South America. Only sporadic cases have been observed upon the continent of Europe and in North America, although Cuba has at times been an active seat of the disease.

At different periods in the past beri-beri has been viewed as either a rheumatic affection or as a constitutional disturbance of nutrition, but the modern and generally accepted view is that it is an infectious disease, probably of miasmatic type, developing under conditions of high temperature and moisture, and presenting the symptomatology of a multiple neuritis. The exciting cause is supposed to be a microörganism, animal or vegetable, though as yet no specific one has been conclusively isolated. The predisposing influences are numerous. The most important is race, the dark races, both native and foreign, suffering more than the white. The disease is more common in males than in females, a fact that is probably to be explained by a difference in the surroundings and mode of life of the two sexes. The largest number of cases occur between the ages of sixteen and twenty-five, and the disease is most prevalent in the months of July and August. The disease notably attacks those of sedentary habits. Debility or depression from any cause, such as previous illness, pregnancy, lactation, or the like, constitutes a predisposing influence. Beri-beri also, in turn, predisposes to the occurrence of complications and the invasion of other disease. In places where the disease prevails the acclimated are less liable to attack than the non-acclimated.

Four types of the disease are described, in accordance with the grouping and intensity of the symptoms: (1) An incompletely developed or rudimentary form; (2) an atrophic form; (3) a dropsical or dropsical and atrophic form; and (4) an acute pernicious or cardiac form. The rudimentary form may set in insidiously, with or without prodromes, including general malaise, fatigue, depression, headache. Frequently catarrhal symptoms are present, soon followed by weakness in the lower extremities, with numbness and edema, and indications of constitutional disturbance. These symptoms may persist

[1] Die Beri-beri-Krankheit: Eine geographisch-medicinische Studie. Von Dr. B. Scheuber, Fürstl. Physicus und Sanitätsrath in Greiz; früherem Professor an der Medicinschule in Kioto (Japan). 8vo, pp. viii, 220. Jena: Gustav Fischer, 1894.

for days or weeks, even for months, convalescence and recovery ensuing gradually.

In the atrophic form the onset of the symptoms may be insidious or abrupt. These consist distinctively in loss of power and wasting of the affected muscles. Improvement takes place slowly, months often elapsing before motility is restored. The dropsical form is characterized by the occurrence of general and widely-spread anasarca, involving the serous cavities as well as the subcutaneous tissues. Recovery is gradual. The acute pernicious form attacks preferably young, robust persons, and is characterized by the occurrence of symptoms of acute cardiac insufficiency. These may set in suddenly in the course of an attack of milder type, although as a rule the course of the disease is from the outset more acute.

The most conspicuous and most constant symptom of beri-beri is the impairment of motion. This begins in the lower extremities, and is of ascending type and of variable degree. Sometimes one side of the body is more affected than the other. In some cases the diaphragm suffers, sometimes the cranial nerves, particularly the pneumogastric. The paralysis is, as a rule, flaccid; exceptionally it is spastic. The irritability of the affected muscles is diminished with both forms of electricity, faradic contractility of both muscle and nerve being lost more rapidly than galvanic irritability. Mechanical irritability of the muscles is also diminished. The paretic muscles waste. Next in importance to these motor manifestations are the sensory symptoms. Cutaneous anesthesia or hypesthesia is almost constantly present. It is of variable distribution, and is proportionate to the severity of the attack, or of the remaining symptoms. Paresthesiæ are common and varied, as hyperesthesia is uncommon. There is little pain, spontaneous or induced. The cutaneous reflexes are as a rule preserved, while the knee-jerks are often wanting. Cerebral symptoms are not pronounced. Circulatory disturbances form an important part of the clinical picture of beri-beri. Among the most common of these are palpitation of the heart, oppression and dyspnea, epigastric pulsation, precordial distress, acceleration of pulse, diminution of arterial tension, cardiac hypertrophy and dilatation, functional cardiac murmurs. The urine is, as a rule, diminished in amount, and in some cases contains albumin. There are, further, symptoms of varying intensity of gastric and pulmonary derangement. The lungs sometimes undergo a peculiar distention. The blood shows no distinctive alteration.

The usual termination of the disease is in recovery. In a proportion of cases this is not perfect; obstinate and incapacitating sequelæ sometimes persist. The most important of these is muscular weakness; others are defective sensibility and circulatory disturbances. The mortality varies with time and place, though always not inconsiderable. In acute cases, death usually results from heart-failure or from paralysis of the diaphragm. In chronic cases, and particularly when complicated with other diseases, death may take place from general exhaustion.

The essential lesions consist in a degenerative inflammation of the peripheral nerves, with a corresponding change in the muscles, and parenchymatous changes in the viscera. In some cases degeneration of the ganglion-cells of the anterior horns of the spinal cord has been observed. The spleen is moderately enlarged in acute cases. Various microörganisms have been found by different observers in the blood and organs of cases of beri-beri, but none has been conclusively demonstrated to possess specific properties.

The prognosis is uncertain, and must be based upon the circulatory condition. The prophylaxis is hygienic, and intimately related to disinfection, drainage, and water-supply. The treatment is climatic and symptomatic. Elevation is to be preferred, and a sea-voyage may be curative. Laxatives have always been looked upon as serviceable. In acute cases, salicylic acid and sodium salicylate have been strongly recommended. Digitalis is an indispensable remedy. In acute cases with cardiac insufficiency, venesection may be resorted to. In chronic cases, arsenic, iron, and quinin are indicated. In atrophic cases, subcutaneous injections of strychnin are useful, and the pareses may be materially improved by electricity.

EDITORIAL COMMENTS.

Hysterical Muscular Atrophy.—The forms in which hysteria may disport itself can in all truth be said to be legion. There is virtually no morbid condition which this peculiar disease of protean manifestation may not reproduce. That the disease is not merely a psychosis, a derangement of psychic coördination, an analysis of its symptomatology must make perfectly evident. The clinical syndrome to which it gives rise is referable not only to the cerebral but also to the spinal and the sympathetic nervous systems as well. In a recent interesting communication, Hirt (*Deutsche medicinische*

Wochenschrift, 1894, No. 21, p. 459) points out that muscular atrophy may not only be of muscular and spinal origin and appear as a manifestation of hemiplegia, posterior spinal sclerosis, diabetes, etc., but that it may also represent a phase of hysteria. The peculiarity of hysterical muscular atrophy is that it is usually limited to one-half of the body, although exceptionally it involves a circumscribed nervous area, such, for instance, as that supplied by the distribution of the sciatic or the radial. Motility diminishes in direct proportion with the atrophy of the muscle-bundles. Under these conditions sensibility varies in the individual case. In exceptional instances it is normal; more commonly it is altered, more particularly common sensibility and the thermal sense, and complete anesthesia may occur. In some cases the atrophic process involves the entire voluntary muscular system, in the absence of appreciable wasting visceral disease. The diagnosis is based upon the psychic attitude of the patient and the occurrence of hysterical or hystero-epileptic seizures. Hirt refers to three cases of general hysterical muscular atrophy and details one at length. This last occurred in a girl of thirteen years, who had suffered with others in the course of an epidemic of hysterical convulsions in a school, and from which recovery apparently resulted. Some time later the girl became ill, presenting general weakness, malaise, and sleeplessness; she became irritable and persisted in remaining in bed and refused nourishment. Soon, however, wasting became a prominent feature, although upon most careful examination no organic disease could be detected. Despite vigorous treatment the girl died, and upon post-mortem examination no lesion other than the muscular wasting could be found.

Life insurance Statistics.—The report of the Medical Examiner-in-chief of the Royal Arcanum for the year 1893 contains some interesting statistics that seem worthy of reproduction. During the year there were received 3455 applications, of which 992 were rejected. Thirteen hundred and five deaths occurred among a membership of 143,192, a ratio of 9.11 per thousand. The largest number of these were distributed as follows: New York, 273; Pennsylvania, 147; Massachusetts, 145; Illinois, 110; New Jersey, 99; Ohio, 78; Arkansas, 14; Minnesota, 8. Of States in which the membership exceeded 500 the rate per thousand was highest in Arkansas (23.1) and lowest in Minnesota (3.5); in New Jersey it was 10.1, in Illinois 10, in Massachusetts 9.7, in Pennsylvania 8.7, in New York 8.6, and in Ohio 8. The largest number of deaths resulted from affections of the brain and spine (212, 16.2 per cent.), the smallest classified number from carcinoma (53, 4.1 per cent.). Tuberculosis was responsible for 194 deaths (14.9 per cent.), diseases of the heart and arteries for 156 (11.9 per cent.), diseases of the lungs, excluding tuberculosis, for 154 (11.8 per cent.), diseases of the digestive organs for 133 (10.2 per cent.), diseases of the kidneys for 125 (9.6 per cent.), casualties for 84 (6.5 per cent.), suicides for 60 (4.6 per cent.). There were 113 deaths (8.6 per cent.) from zymotic diseases; of these, typhoid fever was by far the most frequent. The largest number of cases of tuberculosis occurred in New York (47), with 22 in Massachusetts, 20 in Illinois, 17 each in New Jersey and Ohio, 13 in Pennsylvania, and 10 in Maryland. In States having a membership of over 1000 the death-rate from tuberculosis was as follows: Massachusetts, 2.1 per cent.; Illinois, 1.8 per cent.; Ohio, 1.8 per cent.; New Jersey, 1.7 per cent.; Georgia, 1.6 per cent.; Tennessee, 1.5 per cent.; New York, 1.5 per cent.; Massachusetts, 1.5 per cent.; Michigan, 1.3 per cent.; Indiana, 1.3 per cent.; Virginia, 1.2 per cent.; Wisconsin, 1.1 per cent.; Missouri, 0.9 per cent.; Pennsylvania, 0.8 per cent.; North Carolina, 0.7 per cent.; Connecticut, 0.7 per cent.; Ontario, 0.3 per cent. Ten deaths resulted from appendicitis; six of the cases were subjected to some form of operation.

"Whatever Pays is Right."—The profession of medicine has been praised for, and professors of medicine have taken no little pride in, the fact that personal profit was not the sole end and supreme object of the practice of medicine. Recognizing that, like other men, they must live and, to live, must possess the means of livelihood, physicians have not affected to despise money, and have not hesitated to defend their claims to proper remuneration for services rendered. They have, however, subordinated the money-making or traders' spirit to the scientific or professional spirit, and have not been swayed to adopt a morally doubtful course, because it "paid" to do so. Nor have they thought that evil example excused or relieved from censure those who, knowing the example to be evil, followed it for purposes of gain. It appears, however, that in certain quarters there is entertained a confident belief that this is now to be changed. The report of an important committee of a representative association of physicians contains, as excuse for a course of conduct admitted to be morally censurable, the plea that others do the same thing; and for complete justification of this wrong-doing the statement that a considerable sum of money (elsewhere stated to be eight thousand dollars *per annum*) is gained thereby. For those who admit the force of such arguments, the demonstration is convincing. By the same logic, United States Senators are justified in speculating in stocks the price of which is influenced by their legislative action. "Others do it. It pays." The parallel is complete. While, however, those who have wire-pulled themselves into office in the United States Senate or elsewhere may be willing to acknowledge as their standard of morality, the motto: "Whatever pays is right," we are unwilling to believe that the physicians of America will indorse the action.

Abominable Landscape Advertisements.—Lord Rosebery, the Prime Minister of England, lately asked: "What is to become of our landscape if it is to be simply a sanitary or advertising appliance? Think of the feelings of the illustrious Turner if he returned to life to see the luggers and the coasting ships, which he made so glorious in his paintings, converted into a simple vehicle for the advertisement of a quack medicine."

If Lord Rosebery is offended in England, what would be the state of his feelings if he should travel in the United States? We know a gentleman who will not, if avoidable, make the trip between Philadelphia and New York in the daytime, because of the hideous and nauseating advertisements that glare at him from every barn and field. At Milwaukee last year the medical visitors who perchance visited the Park were astonished at the

filthy deviltry daubed on huge boards for the education of every girl, boy, or woman who might enter.

The worst of all this matter is the double encouragement of disease by first poisoning the minds of the hysterical and pathologically inquisitive, and then inducing more genuine disease by the effects of the vile concoctions. The advertisement encourages the imagination of disease, and then creates the reality by the "cure." Cannot the landscape-advertisement curse be stopped by law?

The Complications of Gonorrhea.—Although the gravity of the complications of specific urethritis has long been recognized, the mode of origin of those not arising by immediate continuity or contiguity has not been clear to the point of demonstration. Recent observations, however, tend to show that these secondary manifestations represent a result of the transference of the specific etiologic factor of the disease—the gonococcus of Neisser. A brief note in THE NEWS of August 19, 1893, p. 217, details the finding by Leyden of gonococci at the seat of an endocarditis occurring in the course of an attack of gonorrhea complicated also by synovitis. Stronger evidence of the same nature is furnished by BORDONI-UFFREDUZZI (*Deutsche medicinische Wochenschrift*, 1894, No. 22, p. 484), who, in a paper read before the Eleventh International Medical Congress, recently held at Rome, related a case of gonorrhea complicated by polyarthritis, in which in the pus removed from an affected joint he was able to demonstrate the presence of gonococci, and with cultures from the second generation of which he was successful in inducing gonorrhea in a subject that volunteered to submit to the experiment. He also refers to a case of gonorrhea complicated by bilateral pleuritis, polyarthritis, pericarditis, and endocarditis reported by another observer, in which gonococci exclusively were found in fluid removed from the pleural cavity.

REVIEWS.

A TEXT-BOOK OF THE THEORY AND PRACTICE OF MEDICINE BY AMERICAN TEACHERS. Edited by WILLIAM PEPPER, M.D., LL.D., Provost and Professor of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania. In two volumes. Illustrated. Vol. II. 8vo, pp. 1046. Philadelphia: W. B. Saunders, 1894.

THE best and most important contribution to Vol. II of Pepper's *Text-book* [which must not be confounded with the more elaborate *System of Medicine*, edited by the same teacher and published by Lea Brothers & Co.] is that of Prof. William H. Welch upon the "Biology of Bacteria, Infection and Immunity." Clear, concise, comprehensive, and accurate, it condenses and elucidates for the practising physician the accepted results of modern research. A thorough grasp of the subject is essential to success in diagnosis and treatment, and hence we warmly commend these chapters to careful and repeated study. Diathetic Diseases, including gout, diabetes, rheumatism, obesity, biliary lithiasis, etc., are well treated by Prof. Henry M. Lyman; Diseases of the Blood, of the Supra-renal Capsules, and of the Ductless Glands, by Prof. Osler, concerning whose work comment is usually superfluous and adverse criticism impossible. Diseases of the Heart and Vessels and Diseases of the Mediastinum have been written of by the Editor. We have been especially pleased with the chapters upon valvular diseases. Prof. J. C. Wilson writes clearly and succinctly concerning Diseases of the Nose, Larynx, Bronchi, and Pleura. In the sections on the upper air-passages much has been sacrificed to brevity. Prof. Delafield treats authoritatively of Diseases of the Lungs and Diseases of the Kidneys. In both articles the pathologic and clinical sections are full and thorough, but those on therapeutics are not satisfactory. Practical Urinalysis is well set forth by Prof J. W. Holland. He fails to give his opinion, however, concerning the reliability of some of the more delicate tests for albumin. The chapters on Diseases of the Mouth, Tongue, Pharynx, Tonsils, Esophagus, Stomach, and Intestines are by Prof. Pepper. They are full and on the whole reliable, though we can hardly agree with the opinion that herpetic pharyngitis is a rare affection. Prof. Reginald H. Fitz's contributions on Diseases of the Peritoneum, of the Liver, and of the Pancreas are admirable in every respect. Probably no other text-book contains an article on the pancreas at all comparable with this.

As a whole we commend the book. Its peculiar excellences are in such articles as Welch's, Delafield's, and Fitz's, but every author has done good work.

THE DISEASES OF CHILDREN (MEDICAL). By H. BRYAN DONKIN, M.D., Oxon., F.R.C.P., Physician to the Westminster Hospital and to the East London Hospital for Children, at Shadwell; Joint Lecturer on Medicine and Clinical Medicine at the Westminster Hospital Medical School. New York: William Wood & Co., 1893.

DR. DONKIN has succeeded in furnishing us with a book of 424 pages, which is interesting, instructive, and somewhat novel in its device. It is hardly suited to students, as, indeed, the preface indicates, as it does not attempt to be complete. For instance, mental diseases are not discussed at all, and some other subjects are also omitted. The author, too, has made no effort to give a full description of each disease considered, but rather to call attention particularly to the points pertaining to children; while he refers more briefly to the symptoms as seen at any age, assuming that these are already known to the reader. Considering this fact, the introductory observations on the method of examining children, and on the special characteristics of diseases in them might with advantage have been fuller. Still, remarks on this topic are found in abundance scattered through the book under the different headings.

Space does not permit an analysis of the various sections of the volume. The amount of attention given to the different diseases seems, on the whole, very fairly distributed, although occasionally one or another of them is cut rather short.

The various subjects are not formally classified under etiology, pathology, and so forth, as in an ordinary text-book, but the diseases are considered somewhat discursively in a pleasant, rather conversational style, with emphasis laid here and there on matters especially important in their relation to childhood, and with a reple-

tion of observations drawn from the writer's wide and long experience. This method of writing makes the book very interesting reading. In fact, the more one reads it the better is one pleased.

We can very heartily recommend the volume to those wishing to add to their libraries a valuable work of reference for frequent consultation. It is not, as we have said, so serviceable to those who wish to limit themselves to one or two works on pediatrics.

CLINICAL LECTURES ON PEDIATRICS. Delivered in the Vanderbilt Clinic during the Session of 1892–93. By A. JACOBI, M.D., Clinical Professor of the Diseases of Children in the College of Physicians and Surgeons of New York. Pp. 195. Stenographic Reports, Bailey & Fairchild. Reprinted from the *Archives of Pediatrics*.

THIS clinical volume represents a fair example of the practical instruction given in the children's clinic of the College of Physicians and Surgeons, as the author remarks, both with the merits and demerits of extemporaneous discourses. Being stenographic reports exclusively, there is a natural charm about them that is not present even in the best systematic writing of the best authors, and while reading them one does not require a vivid imagination to feel the presence of the lecturer, the patients, and the students. There is much in the work that is instructive, and there is authority, learning, and extended experience in every paragraph. The author is a clever diagnostician, an excellent clinician; but when he invades the domain of the strictly surgical affections, the result is sadly disappointing. Instead of condemning all the measures he cannot himself control, as aspirations and injections, the physician should courteously refer all strictly surgical affections to the surgical staff. The time has come for specialism in the surgical diseases of children, and such conditions as spondylitis, congenital dislocation of the hip, syphilitic periostitis, spina bifida, etc., should be dismissed by the physician when a diagnosis has been made. Surgical science has made such swift strides during the last twenty years that it is impossible for the general physician, no matter how skilful, to keep up with the van.

SOCIETY PROCEEDINGS.

AMERICAN GYNECOLOGICAL SOCIETY.

Nineteenth Annual Meeting, held at Washington, D. C., May 29, 30, and 31, 1894.

FIRST DAY—MAY 29TH.

AN Address of Welcome was delivered by DR. FRY, Secretary *pro tem*. Then followed a discussion on "Extirpation of the Uterus in Disease of the Adnexa," which was opened in the affirmative by DR. J. M. BALDY, of Philadelphia. He maintained that the uterus had but one function, to contain and develop the embryo. When the ovaries are removed this function of necessity is destroyed, and the organ becomes a useless one. It has been proved that all patients are not cured after an operation requiring double oöphorectomy. Many complain of pain, metrorrhagia, and muco-purulent leukorrhea. The question as to whether or not patients are cured after hysterectomy when double oöphorectomy has failed, can only be answered by the results of experience. Personally, Dr. Baldy has cured patients by a secondary hysterectomy. He felt certain that the operation of hysterectomy does not increase the mortality above that of double oöphorectomy. On the contrary, he has found that not only has hysterectomy in his hands lessened the mortality very markedly, but it has also rendered the convalescence infinitely smoother, easier, and more satisfactory. Not only is the uterus after double oöphorectomy a useless organ, but he believes that its retention in the body is of disadvantage, or even danger to the patient. The fact that the pelvic floor is more likely to sink to a lower level after the removal of the appendages than after hysterectomy, is a strong argument in favor of complete extirpation. He said that 20 per cent. of all pustubes are of tuberculous origin, and the danger of the disease reappearing in the retained uterus should be a strong reason for removing all of the internal genitalia. Hysterectomy is the preferable operation in a certain percentage of cases. Uterus, tubes, and ovaries should not be removed in all cases of pelvic inflammatory disease; but when, after abdominal section, the womb is found enlarged and diseased, especially if it has not been surrounded by extensive adhesions, the destruction of which leaves large areas of denuded peritoneum, hysterectomy should be the operation of choice. Even in cases in which during an operation the uterus has been largely denuded of its peritoneal covering, hysterectomy should be performed. When there is good reason for believing that the uterus will at some time in the future become the seat of disease, the organ should be removed, or when the danger of hemorrhage may be avoided, hysterectomy should be performed. The abdominal method of operation is the one of choice, because all of the parts are exposed to the eye as well as to the touch, and hence greater accuracy and security can be obtained; and intestinal injuries may be readily discovered and corrected, and complete removal of the adnexa may be insured. Drainage may be avoided by absolute closure of denuded surfaces.

DR. FLORIAN KRUG, of New York, spoke of the results following the Hegar-Battey operation, which were at one time considered gratifying. Its limitations are, however, now recognized. While the appendages were removed, the essential and primary cause of the trouble was retained. The continuance of distressing symptoms is to be attributed to the primary lesion in the diseased uterus, to the effects of premature and artificial menopause upon the sympathetic nervous system, to the irregular and delayed involution of the uterus, and to the adhesions formed between the intestines and raw surfaces in the pelvis. Then there must be added the possibilities of repeated reinfection of the uterus and of ventral hernia, in consequence of different methods of drainage. Histologically, the tubes are but part of the uterus, and their removal is a partial removal of the uterus. Why not go a step further and remove the whole of the diseased organ? The primary situation of the disease is in the uterine cavity, and the tubes are involved by direct continuity of tissue. He asserted that in the hands of those familiar with the technique of hysterectomy the mortality is less than that of celiotomy. He objected to the vaginal method of operation.

DR. H. T. HANKS, of New York, said that whether the uterus should be left or removed in any individual case of diseased adnexa can only be determined when the character of the disease, as well as the condition of the uterus, is considered. In a number of cases all of the troublesome symptoms persist after thorough hysterectomy. Fewer after-symptoms are observed to follow hysterectomy for fibroid uteri than when only the tubes and ovaries are removed. The drainage through the vagina after hysterectomy is the ideal drainage. There are three conditions in which, upon theoretic grounds and from practical experience, he would advocate the entire extirpation of the uterus, in addition to the appendages: when there is an old or recent pyosalpinx, with much exudation, and with a purulent endometritis, or a chronic catarrhal endometritis; when there is a puerperal salpingitis and ovaritis, and probably a puerperal endometritis; when, in removing the diseased tubes and ovaries many adhesions are broken up, and when the uterus is retroflexed or retroverted and held firmly down by exudates—in other words a perimetritis in which the diseased tubes and ovaries, together with a retroverted or retroflexed uterus, are all displaced, diseased, and bound down in Douglas' cul-de-sac by plastic exudation.

DR. BACHE EMMET, of New York, contended that the position that the primary disease may be more thoroughly eradicated by removing the uterus cannot be consistently maintained. Either there is an occlusion of the tube at that point, in which case there can be no infection, as there is no morbid material present, or it may be inert, or, if the tube be opened, it could be drained by the uterine cavity and the patient cured without resorting to ablation. It is maintained that the uterus may still be the seat of symptoms in the absence of actual disease. In such a case there would be reason to suspect an error in diagnosis or that the operation had not been perfect. The difficulty and danger of hysterectomy should always be borne in mind.

DR. W. GILL WYLIE, of New York, would not agree that the uterus should always be removed with the tubes and ovaries. It should be removed, however, in case of malignant disease, in case of fibromata, in case of other intractable disease, and, as a rule, when the patient is over thirty-five years of age. His experience has shown that when the uterus is removed with the tubes and ovaries there is less of the reflex disturbance common in women at the menopause, who have or have had disease of the uterus, than there is in similar cases when the uterus is not removed with the tubes and ovaries. He does not think, however, that the uterus should be removed regardless of its condition.

DR. WILLIAM H. WATHEN, of Louisville, expressed opposition to hysterectomy for diseased appendages in nearly every case. Only in case of malignant disease of the uterus or of a myoma of that organ should the operation be performed. The majority of the women recover permanently after removal of the ovaries.

DR. EDEBOHLS, of New York, said that there are two reasons for removing the uterus with the tubes and ovaries: when it is desired to obtain absolutely good drainage down to the vagina, and when the organ is so diseased that curettage and ventro-fixation would be insufficient to restore it to health.

DR. CUSHING, of Boston, expressed a preference for the glass drainage-tube from above, for the reason that the vaginal drainage from the bottom of the vagina does not reach the lowest portion of the pelvic cavity.

DR. JANVRIN, of New York, maintained that with the improved methods for ablation of the uterus very little shock is added, and, as a rule, the prolongation of the operation is limited to a very few minutes. He would not remove the uterus, however, unless there was some actually diseased condition of the organ visible to the eye.

DR. CHARLES P. NOBLE, of Philadelphia, said that he saw no reason for taking out the uterus unless some definite purpose was to be accomplished. Of course it should be removed in all cases of tuberculosis, or in cases of fibroid and carcinoma, but in all the acute inflammatory conditions of the uterus, unless there is an abscess with destruction of its walls, the organ promptly gets well after the tubes and ovaries are removed. In chronic conditions he would perform hysterectomy if the woman could stand the operation.

DR. PRYOR, of New York, said that removal of the uterus precludes the possibility of further disease of that organ, of displacement and irregular atrophy; the menopause is short; there is nothing left to keep up the neuritis; atrophy of the genitalia is not hastened or exaggerated, and there is entire relief from subjective symptoms. He tries to remove every filament of nerve-tissue about the cervix, and to make the extirpation as complete as possible; he is opposed to the retention of even a portion of the cervix. He believes that as much comfort can be afforded cases of suppurative inflammatory pelvic disease by palliative measures applied from the vagina as can be obtained by removal of the adnexa only.

DR. A. P. DUDLEY recommended hysterectomy in puerperal infection, when the operation must be done hastily to prevent general peritonitis; and in extensive pyosalpinx, and diseases in which the uterus has been adherent so long in the pelvis that to break up the adhesions would destroy the tissue. He does not think it necessary to remove the uterus for catarrhal endometritis.

DR. BALDY, in conclusion, said that he never uses drainage in these cases. The operation of hysterectomy is not to be performed in catarrhal salpingitis and endometritis, but only when there is suppurating disease.

DR. EDWARD K. REYNOLDS read a paper on the "Management of Face-presentations." He said that face-presentations are frequently caused by some mechanical complication of labor, such as a flat pelvis, or a small fibroid in the lower uterine segment, or it may be complicated by prolapsed funis, hemorrhage or eclampsia. In the first stage, with the membranes unruptured, flexion with presentation of the occiput should be secured. The membranes must be preserved, and hence vaginal examinations should be avoided. The patient should be laid on the side to which the fetal abdomen is directed, and if flexion does not take place, the woman should be placed in the knee-chest position. This failing, Schatz's method should be tried. When the membranes rupture early, version may be performed, the back being brought down, or the head may be flexed by manual means. The objection to version is the great fetal mortality, probably as a result of compression of

or traction on the cord. Hence version should only be performed in case of early rupture of the membranes. In the second stage, the treatment depends upon the position of the child. In mento-anterior positions Nature may be left to itself. The fetal heart must be watched, however, on account of the danger from compression of the vessels of the neck. In case operative procedures are required, manual flexion of the head should be preferred. The application of forceps to the face, high up, should be reserved as a last resource, because of the difficulty of its performance. In mento-posterior positions flexion by the hand should be performed. The opinion was expressed that in these neglected cases the vitality of the child will almost invariably be seriously compromised, and the mortality of the abdominal operation is so high that craniotomy should be resorted to.

DR. CHARLES JEWETT said that he regarded the mechanism of face-birth as abnormal and as frequently constituting a serious complication of labor. He thought that presentation by the face is more frequently associated with other complicating conditions, such as small pelvis, large child, prolapse of small parts, than are vertex-births. In the matter of treatment, he makes two general classes of cases: 1. Those in which the head is movable at the brim, or can be made so by pushing it up. 2. Those in which the head is permanently engaged in the pelvis. In the first class, when the chin is anterior, interference is not as a rule required. When the chin is posterior, if all other conditions are favorable, spontaneous birth is generally possible, although the child is more exposed to dangerous pressure than in vertex cases. He would, therefore, in such cases prefer to bring down the vertex under anesthesia. In the second class of cases, spontaneous evolution takes place with but few exceptions. Rotation is to be favored by placing the patient on the side to which the chin points, in conjunction with upward pressure on the forehead or downward traction on the chin during the pains. If the head is immovably fixed in the pelvis, symphysiotomy may be performed, unless the child is weak and the mother's condition is unfavorable. Then craniotomy must be done.

DR. CHARLES P. NOBLE, of Philadelphia, suggested that in neglected anterior positions symphysiotomy might be performed. In case of posterior position he would also prefer symphysiotomy if the child were living.

DR. EDWARD P. DAVIS, of Philadelphia, urged the importance of early diagnosis of this complication. The treatment best adapted to secure spontaneous labor in face-presentation consists in retaining the membranes unbroken until the time of spontaneous rupture, in sustaining the patient's strength by suitable feeding, stimulation, and anodynes, and in placing the patient in a position to favor anterior rotation of the chin. Symphysiotomy is of too recent date to occupy an established place in the treatment of neglected cases. Still he thought it has its place.

DR. MURRAY thought that face-presentations usually resulted from a disproportion between the size of the head and the diameter of the pelvis. He thought that symphysiotomy would tend to reduce the mortality and lead to a great many more spontaneous deliveries.

DR. FRY suggested the value of Trendelenburg's position in performing flexion of the head. He has seen it work very nicely, and believes that it aids in the necessary manipulation.

DR. WILLIAM T. LUSK, of New York, said that it is not easy to flex the head or to rotate the chin anteriorly. If the chin is directed transversely the application of the forceps and the rotation or flexion of the head are very difficult. Symphysiotomy does away with all of these difficulties.

DR. MATTHEW D. MANN, of Buffalo, thought that nearly all of the cases of face-presentation could be treated best by a new position of the head. He thought that by the use of anesthetics we can accomplish all that is done by posture in the treatment of these cases.

In closing, DR. REYNOLDS said that he could not believe that symphysiotomy could ever be indicated in uncomplicated face-labor, unless in the treatment of persistently posterior positions within the pelvis. He would rather sacrifice a few of the children, in whom mortality is at best low, than to perform symphysiotomy.

DR. WILLIAM R. PRYOR, of New York, read a paper on "The Abuse of Trachelorrhaphy." He stated that he regarded laceration as merely a mutilation of the cervix, and that it was impossible for such a mutilation to produce the train of symptoms usually ascribed to it. The cervix is only a sphincter muscle, and it is improper to lay the charge of sterility at its door. He regarded subinvolution as due to the prolonged labor and not as resulting from division of the cervical tissue. While carcinoma of the cervix is becoming quite common, he believed it to be due to the existence of embryonic tissue in the uterus, and not to the tear in the cervix. The only cases that demand trachelorrhaphy are those attended with severe hemorrhage, or those in which the tear extends up to the vaginal junction. In those cases in which the tear is extensive and marked hypertrophy existed, amputation is the operation required. He was not in favor of suturing the cervix, for the reason that this rendered the canal too small for future labors.

DR. HENRY T. BYFORD, of Chicago, agreed in believing that trachelorrhaphy is too frequently performed. In cases of deformity of the cervix Schroeder's operation is the best, for in such cases simple trachelorrhaphy would not meet the requirements. In cases of deep tear, with hemorrhage, sutures should be immediately introduced. Subsequent sepsis may thus be prevented.

DR. J. M. BALDY, of Philadelphia, thought that the pathologic conditions found subsequently to lacerations result from the leukorrheal discharge and not from the tear itself. All lacerations associated with eversion and erosion should be repaired.

DR. CHARLES P. NOBLE, of Philadelphia, did not regard lacerations of the cervix as normal, nor does laceration occur in every parturition. He stated that, according to recent statistics, carcinoma is as common in the negress as in the white woman. Carcinoma occurs usually in women that have given birth to many children. All severe cases of laceration require operation, and in some cases Schroeder's operation is the preferable one.

DR. ENGELMANN, of St. Louis, thought that the extent of injury and the pathologic condition found should be the guide as to the operation required. He did not believe that laceration occurs in every labor; when it does occur,

if the tear extends beyond the crown of the cervix, operation is indicated.

Dr. Gordon said that the operation of trachelorrhaphy has been performed too frequently and without proper forethought for the after-results. He believed that laceration occurs whenever the cervix was originally too small. Now if such a torn cervix be sutured, the original abnormal condition will be restored. In cases associated with hypertrophy and hyperplasia, curetment and the application of pure carbolic acid will be productive of much good.

In closing, Dr. Pryor said that there should be no place in gynecology for the operation of trachelorrhaphy. Other methods would be followed by much better permanent results.

Dr. Edward P. Davis, of Philadelphia, read a paper entitled "Fatal Nausea and Vomiting of Pregnancy," which will be found on p. 597 of The Medical News, of June 2d.

Dr. Edward R. Reynolds stated that he is in the habit of performing abortion at once in such cases, for the reason that there usually exists some structural alterations that require such a radical course of treatment. If the vomiting were allowed to go on, anemia would supervene, and the danger lay in that condition. If the patient be allowed to go on until the absorptive system had lost its power of supplying the body, even abortion would fail to save the patient's life; this in some cases seemed to hasten the fatal issue. If the expectant plan of treatment be adopted great judgment must be exercised.

Dr. W. Gill Wylie, of New York, stated that in his hands the use of steel dilators in this condition had been followed by considerable success. Dilatation and relief of the congestion was followed by good results. There usually existed some pathologic condition to account for the reflex symptoms present. Dilatation, to be effective, should be carried up to the internal os.

Dr. Matthew D. Mann, of Buffalo, spoke of the great difficulty experienced in ascertaining the cause of the condition in any given case. He reported the case of a woman married seven weeks, six of which had been spent in vomiting. After abortion had been induced a fibroid was discovered, which was presumably the original cause of the pernicious vomiting. Dr. Mann advocated the immediate induction of abortion in urgent cases.

Dr. Charles Jewett stated that he had seen many cases of this condition, but had failed in any to discover a pathologic state that could account for the symptoms. He admitted that some histologic changes might have existed. He claimed that great benefit might be derived from dilatation of the cervix, which is both a sure and a safe procedure. He protested against allowing patients to go too far before active measures are instituted.

Dr. A. Palmer Dudley said that he had treated five cases of very obstinate vomiting of pregnancy. He thought that there could be no doubt that the condition is a neurosis, and that the cause lies in some local condition of the generative organs. He was in the habit in such cases of packing the vagina and treating whatever pathologic condition he found to be present. He had found painting of the cervix with cocain to have been beneficial. He also administered cocain internally as well as camphor monobromate.

In closing the discussion Dr. Davis insisted upon the importance of retro-sternal pain and coffee-ground vomit as danger-signals in this condition. Whenever they appeared they called for prompt surgical interference.

Dr. E. C. Dudley, of Chicago, presented a paper on "Myomectomy as a Substitute for Hysterectomy." He first gave a history and a description of the various operations advocated for the removal of neoplasms in and around the uterus, and dwelt upon their relative merits. He stated that his objection to the operation of hysterectomy is that it removed the generative organs from the woman. To prevent this mutilation he has devised an operation for the removal of myomata from the uterus, at the same time preserving this important organ. He described in detail his operation and reported the histories of twenty-five cases in which he had operated for the removal of tumors of various sizes and with varying complications, the whole being accomplished without a single death. In some of the cases the appendages also were removed because of disease; in such cases, however, he would suggest removal of the entire uterus. He believed that in many cases in which the uterus is the seat of a myoma the tubes and ovaries are in a normal condition, and in such cases removal of the tumor is all that was indicated.

Second Day—May 30th.

The Presidential Address, on "The Proper Position of Recent Surgical Methods in the Treatment of Uterine Fibroids," was delivered by Dr. William T. Lusk, of New York. After an historic review of the surgical procedures proposed for the removal of uterine fibroids, he declared his belief in postponing hysterectomy or even myomectomy until every other method of treatment had been given a fair trial. He gave as his reason for such a position that many myomata remain stationary in their growth for years or even disappear spontaneously after pregnancy and curetment. He prefers Apostoli's method for small fibroids. He claimed that great improvement frequently follows palliative measures, while much unnecessary suffering and harm are entailed by the so-called radical treatment. He stated that whenever the uterine tissues are over-nourished the myomatous growths increase rapidly in size, and he suggested the treatment and correction of this hypernutrition as the main indication under these circumstances. He thought the first duty of the gynecologist should be to prevent the loss of the reproductive organs whenever possible. He advocated, when possible, the dilatation of the cervix and removal of the growth through that channel. He thought that the only indications for abdominal hysterectomy is the presence of many adhesions or of multiple tumors or other complications. Taking into consideration the published statistics, he was inclined to believe that vaginal hysterectomy should be preferred to abdominal hysterectomy. He grouped the following disadvantages of the suprapubic method: the disfigurement produced by the cicatrix, the great liability to hernia ultimately, adhesions of the omentum, and the immediate dangers consequent upon exposure of the intestines to the air and the shock. He thought that all tumors larger than a child's head should be removed from above. He did not favor castration for the

relief of fibroid tumors, for the reason that though at times successful, very often the patients would ultimately return suffering as severely as before the operation. In all cases of advanced growths extirpation of the involved organs, either complete or partial, would be the best plan of procedure. Pedunculated growths may be removed by simple ligation; large cystic and multiple growths by the supra-vaginal route, and then, if necessary, hysterectomy may be performed. In the treatment of the stump it seemed to him that the retro-peritoneal method was the one of election.

Dr. Polk, of New York, thought that the tendency is toward myomectomy rather than hysterectomy. He considered the retention of the uterus as of paramount importance whenever possible, and was strongly in favor of myomectomy. He thought it quite as feasible and safe to remove the growth through the peritoneum as through the vagina. He did not think that an accompanying pyosalpinx indicates an inability on the part of Nature to carry on ovulation, and that therefore castration, hysterectomy, or complete extirpation should be performed.

Dr. J. M. Baldy, of Philadelphia, stated that he was in favor of completely removing all the generative organs, and that no uterine tissue should be left *in situ* for fear of forming a nidus for the development of tuberculosis. He did not favor myomectomy, for in that operation complete removal of the diseased tissue, especially *per vaginam*, would be impossible. The vaginal operation also precluded all knowledge as to the condition of the appendages. By the abdominal operation a thorough visual examination of the parts could be made and proper treatment instituted. He contended that myomectomy from above had been abandoned because of the danger from hemorrhage from the divided uterine tissues, which would shrink notwithstanding the application of ligatures. Hysterectomy does away with all such dangers.

While it is true that ligation of the uterine artery might cause shrinkage of the tumor, a collateral circulation might be set up, and in this way the growth receive sufficient nourishment for it to increase in size.

Dr. Cushing, of Boston, said that he could not see why myomectomy should be preferred to hysterectomy. A myomatous uterus was of no benefit to the patient. Whenever there are associated pain and hemorrhage there is always involvement of the tubes and ovaries. He did not favor the vaginal operation, because the diseased tissue could not be removed *in toto*. Only in cases of small tumor should vaginal hysterectomy be performed.

Dr. Gordon advocated conservatism as far as practicable, but would operate whenever operation was necessary. He did not favor vaginal hysterectomy at all, and could not understand why diseased structures should be retained.

Dr. W. Gill Wylie, of New York, said that Dr. Lusk's suggestions were feasible for uncomplicated fibroids only. Generally, however, the conditions are so complicated that hysterectomy is preferable. He is in the habit of removing the whole uterus in cases of unmarried women who do not expect to marry. In young married women he resorts to curetment and palliative measures, such as myomectomy with retention of the tubes and ovaries. In women over thirty-five or forty he prefers hysterectomy. He believed that women suffering from fibroid tumors are more likely to develop carcinoma than other women.

Dr. Henry T. Byford, of Chicago, stated that it had been his intention to read a paper on the subject of the "Results of Vaginal Fixation of the Stump in Abdominal Hysterectomy," but that he would instead confine himself to a brief description of his method of operating and to a discussion of Dr. Lusk's paper. He stated that he agreed almost entirely with Dr. Lusk, and that he had no patience with those operators who advocated complete removal of the uterus in all cases of fibroid tumor. He stated that under palliative treatment he has been enabled to maintain many patients in a very comfortable condition for many years, even ten or fifteen. His treatment consisted in packing, curetment, and so forth, without radical operation. He has never seen any of these cases develop carcinoma. He endeavors to convert the tumors into polypoid growths by the administration of ergot internally, and traction on the growth; then he dilates the cervix and enucleates the tumor. Whenever operation has to be performed, he thought the pedicle should be treated extra-peritoneally above, or else the cervix should be removed, and the stump turned into the vagina and there secured. Drainage was advised.

Dr. Engelmann expressed regret at the manifest feeling against vaginal hysterectomy. This method, he thought, was preferable to the abdominal method, because of the absence of shock and of exposure to the risks of the supra-vaginal method. The danger of vaginal hysterectomy, he admitted, was the difficulty of controlling hemorrhage.

Dr. A. P. Dudley thought that Dr. Lusk's paper tended in the right direction. He thought that myomectomy had come to stay, and said that either method, vaginal or suprapubic, could be employed. In multipara, when the cervix is greatly diseased and the woman is past the meridian, he advocated complete removal as giving the best results.

Dr. E. C. Dudley, of Chicago, thought that the condition found in any given case should be the guide for operation. Hysterectomy is indicated at times, and at other times myomectomy. He thought the dangers of myomectomy very pronounced, and that vaginal hysterectomy offered good results in the great majority of the cases.

Dr. William H. Wathen, of Louisville, preferred myomectomy whenever practicable, so as to save to the woman her childbearing organ.

In closing, Dr. Lusk said he hoped that when the subject should be brought up again the statistical era would have been passed, and the exact position of the two operations have been determined.

Dr. Charles M. Green, of Boston, read a paper on "Rupture of the Uterus; Palliative *versus* Surgical Treatment." He stated that the treatment should be guided by the extent of the tear and the state of the patient. By "palliative treatment" was meant the sustaining of the patient by nourishment and stimulation, the use of antiseptics, and the control of hemorrhage by tampons. Celiotomy does not offer the good results that were hoped for. He reported several cases

in which recovery had taken place after rupture under palliative treatment. It is better to pursue this course than to expose the patient, already in a dangerous condition, to the shock of an abdominal section and the effort to arrest hemorrhage by suturing the uterus. The tissues are usually so irregularly lacerated that perfect apposition is impossible, and sutures would not hold in the friable structures. The palliative treatment he suggested was the use of compressive bandages, cold irrigation, tamponment of the rent with wicking and gauze, and drainage. Celiotomy should never be performed unless the issue seemed to be fatal or the child had escaped into the abdominal cavity and could not be extracted through the natural passages. Then the abdomen should be opened, the child removed, and the uterus sutured. After extracting the child uterine massage, ice-compression, and bimanual pressure should be employed. A tampon, properly employed, would control the hemorrhage. Irrigation through the rent into the abdominal cavity is not indicated unless the amniotic fluid has escaped into the peritoneal cavity. A better plan would be the injection into the cavity of a hot physiologic salt-solution. This would be absorbed and the volume of the blood increased. The peritoneum is very tolerant of aseptic blood, and there is no need of removing it at once. He urged a trial of the palliative method whenever severe hemorrhage does not indicate celiotomy.

Dr. Malcolm McLean believed that palliative treatment is proper in almost all cases. He did not believe in performing version save in those cases in which the child is above the pelvis; then the child should be brought down by version and at the same time the condition of the rent be examined. If the intestines were protruding or the placenta and contents of the bag of waters had escaped into the abdominal cavity, abdominal section should be performed. It is a great mistake to think that rupture of the uterus always indicates celiotomy. Whenever there is recession of the presenting part the operator should promptly draw down the child to prevent its complete escape into the abdominal cavity and the formation of a large hematoma, which would greatly hinder the successful performance of celiotomy should this become necessary.

Dr. William T. Lusk, of New York, thought that in cases of incomplete rupture situated in the posterior wall of the uterus palliative measures are indicated. In cases of tears situated anteriorly a fatal issue generally results. In cases of complete tear he would prefer to bring together the peritoneum and close the wound, so as to give the woman a better chance. The uterus itself should never be sutured. He is not in favor of performing Porro's operation in this class of cases. He advised complete removal of the uterus when the tear is great and the tissue considerably infiltrated.

Dr. Edward R. Reynolds, of Boston, thought that the treatment should vary according to the direction of the rupture. Those occurring elsewhere than in the posterior uterine wall, low down, required, in his estimation, complete removal of the uterus.

Dr. E. P. Davis, of Philadelphia, called attention to the pathology of these cases. He said that rupture of the uterus occurs more frequently in multiparous women who had previously suffered from some septic condition of the uterus, and thus it is impossible to hope for good results unless the uterus is completely removed.

Dr. Polk, of New York, considered these cases as grave in every instance. The most important thing to do was to empty the uterus and see that nothing was left behind. It would be hard to do this through the vagina. He had frequently irrigated through the vagina, but when he had been compelled afterward to open from above he had found that the water had failed to cleanse the abdominal cavity. He thought it was better to deliver by the natural passages, if possible, but to make a small opening above and cleanse in that way. If the uterus is much mutilated he favors complete removal.

Dr. Murray believed in treating the case according as the tear is complete or incomplete. He has seen four cases, two of which were fatal. If the rupture has taken place into the peritoneum it is better to open the abdomen and drain.

Dr. Malcolm McLean insisted that if the fetal membranes are intact, even if the rupture has been into the peritoneum, they are protective, preventing the introduction of infectious material, and under these circumstances the case should be treated differently. The simple oozing of aseptic blood into the peritoneal cavity can do no harm.

Dr. W. Gill Wylie, of New York, read a paper on "The Influence of Laceration of the Perineum on the Uterus, and the Operation for its Repair." He had no doubt that there is much yet to learn as to the results of laceration of the perineum, and the best methods of repair. For some time past he has been pursuing extensive studies in this direction, and believed that he had now arrived at the best method of operating upon an old laceration, especially when a rectocele is present. The general supposition is that in all ruptures of the perineum into the rectum there must necessarily follow a displacement of the uterus. This, however, is a mistake. If the rupture take place in the median line, even though it extend through the sphincter muscle of the bowel, there is no subsequent displacement of the uteri. If, however, the levator ani muscle is separated on both sides, then the continual straining at stool will eventually bring down the uterus. He was of the opinion that the anatomic facts in regard to the various axes, abdominal, pelvic, rectal, and anal, are not properly understood. If they were it would be plain to all why displacements of the uterus occur in certain forms of lacerations and not in others. The function of the perineum is not to keep the uterus in position, but to sustain the relation of the rectum and anus. When the perineum is destroyed, the continual forcing downward of the contents of the bowel, the normal resistance being removed, results in the formation of the rectocele. To restore the normal condition it becomes necessary to reunite the ends of the severed muscles and to dissipate the sulci on either side over the rectocele, thus strengthening the wall and thereby preventing the pouching. The straining at stool is the cause of the retroversion and prolapse. The uterus first becomes wedged in back of the utero-sacral ligaments, and not being able to free itself, further straining causes further extrusion of the organ. For the relief of this condition Dr. Wylie performs a modification of Tait's flap-splitting operation. This consists in a narrowing of the posterior vaginal

wall, and a picking up of certain tissues. The levator ani and the fascia in the depressed sulci on either side must be denuded and drawn up. The denudation must be deep enough to expose the dense white tissue. The structures must then be firmly drawn up with silver-wire sutures, the last three or four being entirely within the vagina. The sutures are left *in situ* for two or three weeks.

DR. CHARLES P. NOBLE, of Philadelphia, has found that when tears extend into the rectum they are invariably in the median line, and this probably is the reason why the uterus does not prolapse. He is always able in operating to find the fibers of the torn levator ani muscle, and he did not think that the support of the pelvic tissues depends upon a little white fibrous tissue, but upon the integrity of the levator ani muscle.

DR. A. J. C. SKENE, of New York, agreed with Dr. Wylie in his statement that complete lacerations do not cause prolapse. Another reason why there is no prolapse with lacerations in the median line is that compensation takes place in the levator ani muscle, the pelvic floor being drawn up, and prolapse consequently being prevented. He does not recognize the condition of so-called rectocele; what he finds in these cases is a mass of hemorrhoidal veins, and the best operation to correct this condition is Emmet's.

In closing, DR. WYLIE said that he could not see how it would be possible for any operation done in the median line to accomplish any good when the laceration has occurred in the sulci.

DR. FRANCIS DAVENPORT, of Boston, read a paper entitled "The Ultimate Results of the Treatment of Retrodisplacements by Pessaries." He admitted that there are certain objections to the use of the pessary, but thought that these have been exaggerated. Most women can wear pessaries without discomfort; all that is required is a certain amount of skill in the fitting of the instrument. One objection is that the pessary requires frequent attention from the physician; another is that it is a foreign body, and necessarily unpleasant; still another is that it does not cure, and must be worn for the rest of the patient's life. He gave the history of fifty selected cases of retroversion that had been treated with pessaries. Ten were completely cured, the uterus being held in normal position. Nine were benefited and symptomatically cured. Thirty-one were now going without pessaries, the uteri being in normal position, although they still had some symptoms. He stated that this treatment gave 20 per cent. of absolute cures. The shorter time the displacement has lasted, the sooner the cure. In cases in which operation is objected to, he thought a fair trial of the pessary should be made for several months, or a year.

DR. CUSHING, of Boston, thought that the usual statistics given on this subject are valueless, that too often the symptoms are treated, and not the cause. He was sure that but few cases required Alexander's operation. He believed in giving a fair trial to every form of treatment, including the pessary, and if then the uterus would not remain in position, and the symptoms continued, the abdomen should be opened and the trouble corrected.

DR. CLEMENT CLEVELAND, of New York, said that he believed in the use of the pessary and in Alexander's operation. He thought that there was a field for both, and that Alexander's operation was the most beneficent operation, and had come to stay. He had done the operation over forty times, with the most gratifying results.

DR. EDEBOHLS, of New York, contended that the only cases in which the pessary could be used are those in which there are no adhesions, and in which the tubes and ovaries are in a normal condition. In the other class of cases, which is by far the largest, his plan is to shorten the round ligaments. He has done this seventy-five or eighty times and always with success. There was always an anatomic cure, but not always a symptomatic one.

DR. WILLIAM H. WATHEN, of Louisville, presented a communication entitled "Retro-peritoneal and Intra-ligamentous Tumors of the Uterus and Adnexa." Although cysts of the paroöphoron and retro-peritoneal uterine myomata have not a common etiology, he considered both varieties of tumors together for the reason that the technique of the operation for their successful removal is practically the same. With but few exceptions, cysts that open up the layers of the broad ligament, and burrow deeply into the pelvic and retro-peritoneal connective tissue probably arise from remnants of the mesonephron in the paroöphoron. Either the cystic or the solid tumor may separate the peritoneum anteriorly and lie in front of it, attached to the bladder or to the fascia and muscles of the abdominal wall. In some cases the separation of the peritoneum may be so extensive that the tumor may be removed and enucleated through a median incision between the tubes and umbilicus, without wounding the peritoneum. The separation, however, is usually from the posterior pelvic and abdominal walls. The tumor, having passed beneath Douglas' sac, separates the mesorectum, mesocolon, or mesentery of the small intestine, and lies under the appendix, cecum, or ascending colon, and between these and the wall. The capsule is full of enlarged vessels, which bleed freely during the process of enucleation. These vessels may even be as large as sinuses, especially when the tumor has unfolded the mesentery of the bowel. The intra-ligamentous or retro-peritoneal tumors should not be removed without an intimate knowledge of the normal relations of the pelvic and abdominal viscera to the surrounding tissues and to each other. These tumors are mainly supplied with blood from the ovarian and uterine arteries, and successful enucleation depends largely upon an accurate ligation of these vessels. The dangers attendant upon the operation are hemorrhage from divided adhesions, from the capsule of the tumor, from the denuded surface of a myoma, from injury to the spermatic and uterine arteries, the iliac arteries and veins and the inferior vena cava, and wounding of the ureters, bladder, or intestines. The causes of death are hemorrhage, shock, and sepsis. To prevent injury to a ureter that may be in front of the tumor, it is best to incise the capsule and introduce ligatures parallel to the abdominal wound. Hemorrhage will be greatly lessened by careful enucleation close to the cyst-wall or the substance of the myoma, thus pushing the vessels in the capsule and connective tissue away from the tumor, without wounding them. In some cases by enucleating close to the tumor and the uterus it may be possible to perform total hysterectomy without ligating the uterine

arteries, which are pushed aside and left in the pelvis uninjured. Great care must be observed in separating the tumor from the bladder and the intestines, to avoid wounding or so injuring their coats as to give rise to sloughing. When the pre-vertebral space is reached the dissection must be done carefully, hugging the tumor, to avoid the ureters and deeply seated vessels. Hemorrhage from the substance of a soft cavernous myoma may be controlled by firm pressure with gauze or ligation *en masse*, the ligature being introduced deeply under the bleeding vessels by means of a long curved needle. Adhesions should be separated if possible between forceps or ligatures. The cyst should be tapped before enucleation is begun, for when this is done the caliber of the vessels in the capsule is reduced. If hysterectomy is necessary, total extirpation is preferable. If possible, it is best to ligate the uterine arteries to the outside of the ureter, before they give off branches to supply the upper portion of the vagina and cervix. There is no fixed opinion as to the treatment of the sac-cavity. It may be drained through the vagina, through the abdominal walls, with or without suturing the capsule to the abdominal wall, or it may not be drained at all—as when hemostasis has been nearly perfect and the operation aseptic. In total extirpation the vaginal vault should be closed by interrupted sutures.

THIRD DAY—MAY 31ST.

DR. MATTHEW D. MANN, of Buffalo, read a paper on "Inflammation of the Ureters from a Medical Standpoint." He contended that inflammation of the ureters is much more common than is generally supposed, basing his belief upon careful observations extending over a period of many years. Some of the the causes of such inflammations are pelvic cellulitis, suppuration in and around the pelvic organs, gonorrhea, and labor. The symptoms are pain and tenderness on pressure over the course of the ureters. Whenever these are present the urine should be examined. If its reaction is acid and pus is present, ureteritis should be suspected. Injury to the ureters occurs most usually when the head pushes down the anterior lip and drags down the bladder behind the pubes; it also takes place in instrumental deliveries. Ureteritis is frequently mistaken for inflammation of the bladder. It may arise from any condition causing obstruction to the flow of the urine. Gonorrheal cystitis may extend to the ureters. Dr. Mann expressed the belief that the pain and discomfort which persist in many cases after the removal of pus-tubes are due to unrecognized inflammation of the ureters. The vesical irritation associated with anteflexion is not so much due to the displacement as to the dragging on the ureters. An examination of the urine would prove this. The first symptom noticed in ureteritis is a slight catarrhal condition of the urine. If the ureters should now be palpated they will be found to be thickened and sacculated. The bladder is not generally affected, but there may also be cystitis. The pain is most commonly located on the left side, and is burning and cutting in character, and much aggravated at the menstrual period. The pain may be so severe as to make walking impossible. Increased frequency of micturition is the most common symptom. A curious symptom is a distaste for water. Bilious attacks and periods of great depression of spirits occur. The diagnosis is to be made by an examination of the urine and by palpation of the ureters. The urine is scanty and contains pus-cells and blood-cells; it is markedly acid in reaction; it contains a slightly increased amount of mucus. The treatment is constitutional, local, and surgical. The constitutional treatment includes hot baths, dry hot air, and the free use of water and alkalies; then medicines to increase the secretion of urine, and antiseptics to be excreted with the urine. Finally, the formation of a vesico-vaginal fistula at times gives marked relief.

DR. J. M. BALDY, of Philadelphia, expressed the opinion that inflammation of the ureters is very rare. When it exists, the only thing to do is to give alkalies. He thought that sweating the patient would concentrate the urine and thus aggravate the condition.

DR. A. P. DUDLEY maintained that there is one class of cases in which a mistake in diagnosis might be made, and that was between appendicitis and ureteritis. He believed that the disease begins in the ureter itself. He said that pressure upon the ureter from the various forms of disease of the appendages might cause obstruction of its caliber and result in disease in the kidneys.

DR. FORD thought that ureteritis occurs frequently in young women in whom there is no particular disease of the appendages. He agreed with Dr. Mann that the causes are mainly dietetic, lithemic conditions being brought about which caused irritation of the ureters. He had had good results from high enemata of water, introducing from three pints to two quarts. These acted as diuretics. Everything should be done to secure perfect oxidation.

DR. CUSHING, of Boston, thought that the condition probably existed in cases of obscure pelvic pains with frequent micturition and irritable bladder.

DR. CHARLES P. NOBLE, of Philadelphia, read a paper entitled "Symphysiotomy *versus* the Induction of Premature Labor." He gave an historic review of the subject with statistics showing the slight inherent risks to the mother when symphysiotomy is performed. In cases of contracted pelvis he prefers to allow the patient to go to full term, then to perform symphysiotomy and deliver the child by a high forceps-operation.

A paper by DR. THOMAS A. ASHBY, of Baltimore, on "The Influence of Minor Forms of Tubal and Ovarian Disease in the Causation of Sterility," was read by title.

NEWS ITEMS.

N. S. Davis Professorship in the Northwestern University.—Mr. William Deering, a prominent business man of Chicago, has donated $50,000 to the medical department of the Northwestern University of Chicago, for the establishment of a professorship to be named after Dr. N. S. Davis, otherwise known as the Father of the American Medical Association.

The Columbus Medical Journal, since the 1st of July, has been enlarged, and appears every two weeks instead of monthly, as heretofore. A commendable departure will be the elimination of interleaved advertisements. Dr. R. Harvey Reed is the new Editor.

Dr. Carl Posner, one of the editors of the *Berliner klinische Wochenschrift*, has been appointed Professor of Internal Medicine in the University of Berlin.

THE REACTIONS OF NUCLEO-ALBUMIN (ERRONEOUSLY STYLED MUCIN) WITH THE COMMONLY EMPLOYED URINARY ALBUMIN-TESTS: THE DIFFICULTY OF DISTINGUISHING THESE REACTIONS FROM THOSE OF SERUM-ALBUMIN, GLOBULIN, Etc.

Remarks on the Occurrence of a Normal, Constant Trace of Albumin in the Urine.[1]

BY D. D. STEWART, M.D.,
OF PHILADELPHIA;
CLINICAL LECTURER ON MEDICINE IN JEFFERSON MEDICAL COLLEGE.

IN a paper[2] read before the Society for Clinical Research, I drew casual attention to certain fallacies attending the use of delicate tests for the detection of serum-albumin in urine, laying stress on one especial source of error which I regarded as the most important and misleading. This related to the frequent presence normally of nucleo-albumin in amount sufficient to react to nearly all of these tests, such as Tanret's, Millard's, and Sebelein's reagents, and to all other similar test-solutions containing tannin, mercury, or a vegetable acid. This also applied to picric acid, especially the citrated solution, and to metaphosphoric acid, but particularly to trichloracetic acid, now much in vogue as a reagent for the detection of small amounts of serum-albumin in the urine.

I pointed out that a reaction could be so commonly obtained from several of these, with the urine of the healthy, that unless this were regarded, it were unquestionably better in clinical work to depend upon the less misleading, if also less delicate time-honored methods, especially that by ebullition, with, if necessary, the addition of acetic acid.

I had at one time regarded the slight reaction so frequently obtained with healthy urine, as indicative of the existence of a physiologic albuminuria, but within the past year or two the result of certain experiments of my own and the work of others in the same field has rather tended to convince me that in the vast number of cases the substance reacting to the very delicate tests is a mucoid body probably originating from the cellular elements of the extra-renal passages. My reasons for so believing I have entered into elsewhere,[1] so need not here detail them. Lastly, re-experimenting with the delicate tests, in investigating certain cases of non-albuminuric nephritis, I have been especially interested to determine if the nature of the reaction often obtained by several of the very refined of these, and presumably not due to serum-albumin or to globulin, could be exactly determined, and whether it be due to a mucoid body, settled.

Exact experiments with various percentages of artificially added nucleo-albumin to albumin-free urine seemed the most satisfactory mode of ascertaining with certainty the nature of its reactions, and their differences from those of serum-albumin, serum-globulin, the albumoses and peptone, bodies with which there is no doubt that nucleo-albumin has repeatedly been generally confused by many of the most accurate and perhaps all of the careless workers in urinalysis. As stated in the paper previously referred to, urinary nucleo albumin, which is now regarded as identical with the nucleo-albumin of the bile, is not true mucin, though still improperly so termed by many who are unaware of the important differences in these bodies which separate them both chemically and physically. Briefly, these bodies are distinguished in that concentrated solutions of mucin are mucilaginous and thready; with acetic acid mucin gives a precipitate insoluble in excess, while mucin, as a glycoproteid substance, after prolonged ebullition with dilute mineral acids yields, besides an albuminous body, a carbohydrate which reduces copper hydroxid.[2] Magnesium sulphate, also, is without precipitating effect upon solutions of mucin, totally unlike the case with solutions of nucleo-albumin. These differences in reaction have shown that it is doubtful if true mucin is ever present in the urine, and that the reacting body is in reality nucleo-albumin. This fact is of the highest clinical importance, as apart from a local nucleo-albuminuria,[3] all the in-

[3] That is, nucleo-albumin derived from the cells of some part of the urinary tract.

dications point to the fact that a nucleo-albuminuria, the nucleo-albumin of which is underived from any portion of the urinary passages, is of no uncommon occurrence. The clinical aspect of nucleo-albuminuria cannot now be discussed; suffice it here to state that it is a subject worthy of attention, and the study of which is in the line of the elucidation of not a little that is obscure concerning the question of albuminuria without nephritis.

In the course of recent experiments with urine from the healthy, specimens of day and food urine were often encountered which, with proper precautions to exclude precipitation of urates, gave a sharp cloud after appropriate treatment with acetic acid; but it was always found impossible to obtain by filtration, although dilution was first practised,[1] sufficient of a precipitate in this manner to be utilized for experiment, such really small amounts did the precipitate represent.

As urinary nucleo-albumin is unobtainable in trade the experiments were made with nucleo-albumin (Merck's) derived from bile. This substance is regarded as identical, both chemically and in point of its various reactions, with nucleo-albumin occurring in urine. This body was found to be very slightly soluble in distilled water, and much more soluble in neutral or in alkaline saline solutions. With none of these in concentrated solution did it have a mucinous appearance, and the other tests, including ebullition with a dilute mineral acid, and subsequent testing of the precipitate for a reducing substance, showed that the body contained no true mucin. In the solid state it gave the xanthoproteic reaction, but reacted doubtfully to Adamkiewicz's reagent, and gave no response to Millon's, Liebermann's, or to the biuret test. This last was also examined for in strong solution, without result. This lack of reaction to certain of these color-reagents is interesting not only as a point in separating the nucleo-albuminous response from that due to other albuminous bodies, but also in indicating that the nucleo-albumin employed in the experiments made by Müller,[2] in which he obtained all the color-reactions, was contaminated with a second albuminous body.

[1] Because of the soluble effects of certain of the urinary salts, it is more easy to remove the mucoid precipitate produced by acetic acid in dilute urine than in one of ordinary gravity. It is also on this principle that the interesting fact pointed out by Reisser is explained, that if to a specimen of urine which my be clouded by the addition of acetic acid, a second is added which is not so affected, no cloud may be produced by testing the mixture.

[2] See Neubauer and Vogel (loc. cit.). It is there stated that Müller obtained all the color-reactions with nucleo-albumin. The varying results there given can only be so explained. It is stated also that one observer noted that heat was without effect upon a solution of nucleo-alhumin, and a second the contrary. The experiments I detail were made in a manner precluding error of this sort.

Acting upon the fact that neutral salts, such as NaCl, AmCl, Na_2SO_4, and sodium acetate, serve to maintain the nucleo-albumin of the urine in liquescence, no difficulty was encountered in obtaining a perfectly clear solution of this substance. The diluents used for the experiments were saline solutions of distilled water and normal acid urine; the former was prepared to contain approximately the amount of mineral salts, represented by NaCl, and a less amount of sodium acetate, that exist in urine of ordinary gravity. No allowance was made for urea, and this is regarded as being without auxiliary solvent effect. Specimens of very clear, filtered, morning urine from normal individuals were employed which, unfiltered, gave no reaction with trichloracetic acid until after five minutes' contact. Nucleo-albumin was added in proportions varying from approximately 0.4 per cent. to 0.02 per cent. In the preparation of the solutions this substance was first triturated with a small quantity of the diluent, subsequently thoroughly agitated with the total amount, and on each occasion thoroughly boiled for some minutes.[1] After a large number of filtrations a clear solution could be obtained. When an amount upward of 0.4 per cent. was added, some slight residue always remained on the filter; with smaller portions solution of the whole quantity was readily obtained, although filtration in removing turbidity naturally coincidently withdrew a certain amount in fine suspension.

A very large number of experiments, approaching several hundred, were made with these solutions. A variety of tests in common use for the detection of albumin in urine were employed: ebullition with and without the addition of acetic acid; nitric acid; acetic acid and potassium ferrocyanid; metaphosphoric acid; plain and acidulated saturated solution of picric acid; Millard's reagent; trichloracetic acid, and a test-solution of mercuric chlorid with tartaric acid, a newly introduced reagent regarded of greater delicacy than Tanret's solution. Besides the employment of the color-reagents, notably the biuret test, the behavior of magnesium and ammonium sulphates in neutral solution was also ascertained.

The reactions with acetic and citric acids should be first mentioned. Citric acid was employed in both saturated and dilute solution. With these in all the various strengths of nucleo-albumin solution experimented with, a sharp contact-ring was ob-

[1] Lest ebullition have any decomposing effect upon the nucleo-albumin, altering its character, which, however, was not anticipated, in the form of menstruum employed, all the experiments detailed with the boiled solutions were repeated with solutions of similar strength prepared without heat. The results were identical. This likewise showed the absence of contamination by ordinary albumin, more than traces of which would, of course, be removable by boiling.

tained with a more or less diffused haze above. Acetic acid was used in the form of the liquid glacial acid, and in 2 per cent. and also in 25 per cent. strengths. The reaction with acetic acid was similar to those obtained with urines containing the mucoid body. The acid was applied both by the contact-method and by the addition of small amounts to 10 c.c. or more of the test-urine. A contact-ring was obtained with all strengths of acid, with a cloud above, though a less marked contact-reaction occurred with the undilute glacial acid, in which latter, indeed, nucleo-albumin can itself be dissolved. A cloud occurred instantly on the addition of small amounts of acid to the body of a few centimeters of test-solution, its intensity and rate of appearance varying directly with the amount of nucleo-albumin present, and inversely with the proportion of salts present.

A reaction occurred with HNO_3, employed by the contact-method, with all strengths of nucleo-albumin solutions. It was still apparent as a slight contact-cloud in a dilution giving but a trifling haze with plain picric acid. With solutions approximately 0.1 per cent. or more, though carefully underlaid by the acid with a capillary pipet, the whole stratum of solution soon became opaque, and after standing a short time a deeper, opaque ring was found at the point of contact of the two liquids. With less strengths than 0.1 per cent., such as from 0.05 to 0.08, it was easy to obtain an instantaneous contact-reaction quite like the ordinary serum-albumin ring, although it lacked the appearance of denseness; the latter, if of any depth, usually has little or no opacity above, with these strengths of solution so tested.

A slight contact-cloud was still apparent with the weakest solution used, approximating 0.2 per cent., a dilution which gave but a faint contact-haze with unacidulated picric acid after standing a few moments. A few drops of fuming HNO_3 added to a few centimeters of urine also produced a slight opacity in urine containing this same dilution of nucleo-albumin.

A combination of acetic acid and potassium ferrocyanid, a test for serum-albumin in the urine first proposed by Pavy, and now much in use, gave the ordinary albumin-reaction, entirely indistinguishable from that of serum-albumin.[1] This reaction was still apparent in the least strength tested. The reaction was decided at 0.05 per cent., and was still apparent at 0.025 per cent.

The various strengths of nucleo-albumin solutions also reacted similarly to metaphosphoric (glacial) acid. This reaction was in no way distinguishable from that of serum-albumin.

With considerable amounts of nucleo-albumin present, the whole solution above the piece of glacial acid became almost instantly opaque. With small amounts an almost instant contact-opacity occurred, typically such as is produced by serum-albumin, and gradually diffused from the portion of acid throughout the fluid. If but traces of nucleo-albumin were present, but still sufficient to react to acetic acid, though scarcely appreciable with unacidulated picric acid, the contact-response was delayed, not appearing for from two to three minutes, but soon becoming decided with longer contact.

A decided reaction was obtained with a saturated solution of picric acid, and with the citrated solution, indistinguishable in appearance from the contact-response with ordinary serum-albuminous urine. The ring was most sharply defined when the nucleo-albumin solution was of not too low a gravity (above 1010). No reaction, save a tardily appearing contact-haze, occurred, however, to unacidulated picric acid with a nucleo-albuminous dilution approximating 0.02 per cent., although the citrated picric acid still gave a ring, and a response was still evident to metaphosphoric acid, and very markedly to trichloracetic acid, to Millard's, and to the mercuric test.

I had before shown that unacidulated picric acid solution reacted to the urinary mucoid body,[1] which is contrary to the view of Sir George Johnson. These experiments finally settle the question.

With Millard's reagent nucleo-albumin solution continued to give a sharp contact-reaction with a dilution at which plain picric acid had entirely ceased to react.

With trichloracetic acid up to the weakest dilution of nucleo-albumin employed, a sharp contact-reaction was obtained. With a dilution approximating from 0.025 to 0.04, with which unacidulated picric acid gave no more than a contact-haze, a markedly broad, opaque ring was apparent with trichloracetic acid.

With the tartrated mercuric reagent a similar reaction was obtained as that of the others, although it was found that this reagent did not compare in delicacy with trichloracetic acid.

It is now of importance to study in greater detail the reactions of nucleo-albumin with these albumin-tests, and to determine, if possible, how they may be differentiated from the reactions of serum-albumin, serum-globulin, the albumoses, and peptone, but especially from the first named. It will be recalled

[1] Even so careful a chemist as Hammarsten (Text-book of Physiological Chemistry) does not speak of the similarity of reaction of nucleo-albumin and serum-albumin to either metaphosphoric acid or to the reagent of acetic acid and potassium ferrocyanid, in recommending these latter for the detection of albumin. No writer refers to confusion arising from the employment of metaphosphoric acid.

[1] By the removal of the reacting body with acetic acid in the cold. See American Journal of the Medical Sciences, December, 1893; THE MEDICAL NEWS, April 14, 1894.

that as thorough ebullition was invariably practised with the acid artificial or natural urine in preparing the nucleo-albuminous solutions, more than traces of ordinary albumin could scarcely be present; and that as it was necessary to repeatedly filter to obtain a clear solution for testing, more than traces of the albumoses, or so-called urinary peptones, if present, would also be removed; as filtration of the solution was repeatedly done not only while hot but after it was thoroughly cooled

The likeness of nucleo-albumin to urinary albumose or peptone is striking in several particulars. That the one has in the past often been mistaken for the other, I have no doubt, in view of the identity in many of the reactions of the two. This curious similarity in reaction of these bodies probably depends upon a close kinship. As Wright[1] and others have shown, nucleo-albumin is identical with cell-fibrinogen, which under the influence of ferments (proteolytic) is decomposed into a nuclein-moiety and albumose, or so-called peptone, the last of which is not infrequently present in the urine in cases of active leucolysis. It is conceivable and probable that traces of the albumoses are also present in the urine in conditions leading to proteolysis in the bladder of the urinary nucleo-albumin, through the action of pepsin and trypsin, which are normally present in the urine, and by the aid as well of formed enzymes. But that nucleo-albumin is not identical with the albumoses or peptone is shown by its ready precipitation by acetic and other of the vegetable acids, and by the fact, as I have ascertained, that it will not give the biuret-reaction. This last seems a very positive mode of differentiating it from the other albuminous bodies.[2]

Its differentiation from ordinary peptone is quite easy, as I have found that by saturating hot urine containing nucleo-albumin with ammonium sulphate, all traces of nucleo-albumin are removed, so that no response can be subsequently obtained with trichloracetic acid.

Its similarity in several points to serum-globulin is also quite striking. Its presence in the urine, I believe, has often been mistaken by those who are unaware that globulin very rarely, if ever, exists without the coincident presence of a greater amount of serum-albumin.[3] Like serum-globulin, if mucoid nucleo-albumin is present in some amount in the urine, as I have found is common in specimens of the day-urine (after food and exercise), it may not infrequently be precipitated from solution by considerable dilution of the urine with water, lessening the soluble effect of the urinary salts, or by dialysis to a very low specific gravity; or, like globulin, it may be readily thrown down by magnesium sulphate after neutralization with ammonia and separation of the earthy phosphates.

A strikingly interesting and important feature of the reactions of mucoid nucleo-albumin to the albumin-tests is the influence of heat. Although the presence of this body may be readily shown by the intelligent use of acetic acid or other of the vegetable acids, in the cold, yet without the assistance of heat it would be quite impossible by any reagent, were the reaction decided, save perhaps the biuret-test, to definitely assert that serum-albumin is not also present in some amount.[1] Heat with every test employed save two—the metaphosphoric acid, and acetic acid and potassium ferrocyanid—tends to diminish a nucleo-albumin reaction if the amount of this body present is in moderate or small percentage, such as is likely to be encountered in the urine. This result was invariable with a percentage upward of 0.15. With the presence of greater amounts, the soluble effect of heat was much less apparent; and with a percentage of from 0.3 to 0.4, heat was either without influence or slightly increased the reaction previously obtained. This effect, also, I have found varies in degree with different specimens of the diluent of approximately the same degree of acidity containing not only different strengths of nucleo-albumin, but the same amount. The cause of this variation seems largely due to the character and amount of salts present.[2] Albumin-free[3] urines, and artificial urines experimented with, showed this variation with different percentages of nucleo-albumin. The reagents, whether HNO_3, picric acid, trichloracetic acid, or others, seem to hold, after precipitation, a portion of the nucleo-albumin, so that a temperature approaching the boiling-point, even with very small percentages of nucleo-albumin present, will not entirely dissipate the precipitate.

[1] See a paper on "Tissue- or Cell-fibrinogen in its Relations to the Pathology of the Blood." A. E. Wright, Lancet, March 5, 1892.

[2] It would become a clinical mode of differentiation of great value were the biuret-reaction for albumin one of any delicacy.

[3] This seems well established, and yet not infrequently in urine-reports of cases it is noted that serum-globulin but no serum-albumin is present. In these instances the reacting body is probably nucleo-albumin, which, I believe, is nowhere noted as likely to be a confusing factor.

[1] This is important, in view of the frequent coëxistence of serum-albuminuria with a so-called mucinuria (nucleo-albuminuria).

[2] It is interesting to note that with approximately a 0.2 per cent. nucleo-albumin solution, containing NaCl, and a less amount of sodium acetate of a sp. gr. of 1017, the boiling-point has a slight precipitating effect. A further addition of a small amount of sodium acetate entirely prevented this precipitation in a second portion. Even without the presence of salts nucleo-albumin in small amount is apparently rendered more soluble by heat. A small amount shaken with distilled water, left, after a single filtration, a cloudy solution. Boiling at once cleared the latter.

[3] Save to trichloracetic acid.

Heat was most commonly applied in the manner detailed in the former paper,[1] by immersing the test-tube in hot water to a point beyond the upper line of fluid. In the trichloracetic-acid experiments there mentioned the bath was not always quite at 212° F., as so high a heat was not thought necessary. I was then unaware of the soluble effects of high heat upon traces of this mucoid body, accepting, as is commonly taught, that nucleo-albumin reacts to heat very much as does serum-albumin.[2] It evidently requires a temperature at or quite near 212° F., and prolonged—some minutes' contact—to insure a partial solution even with small percentages of nucleo-albumin. This is especially the case with trichloracetic acid. Nitric acid, and especially acidulated picric-acid solution, likewise retains a certain amount of the precipitant. With unacidulated picric acid the soluble effect of heat is more decided. The contact-coagulum obtained with it is dissipated to a greater degree by the aid of heat than with the others.

With potassium ferrocyanid and acetic acid, and especially with the metaphosphoric-acid test, however small the percentage of nucleo-albumin present, the soluble effect of heat is not evident. On the contrary, with the latter, heat tends to intensify the reaction obtained, so that it cannot in any manner be distinguished from that of serum-albumin. For this reason the clinical use of these reagents as precipitants of albumin must be regarded as absolutely untrustworthy, and should be unqualifiedly condemned.

It is important to study the effects of heat upon unprecipitated urine-solutions of nucleo-albumin. Heat, in any proportion of nucleo-albumin (in undiluted acid urine of ordinary gravity), upward of 0.15 per cent., is totally without precipitant effect. A few drops of dilute acetic or other acid which, added at ordinary temperature, cause a sharp cloud, are without precipitating effect upon the boiling urine. As cooling occurs, clouding results. When nucleo-albumin is present in proportion of from 0.3 to 0.4 per cent., whether ebullition was previously employed in obtaining the solution or not, clouding always resulted without the addition of acid on boiling. This behavior of the various strengths of nucleo-albumin, with urine as a menstruum, was invariable in a large number of experiments. It shows that when nucleo-albumin is present in amount approaching saturation, heat exerts a totally different effect from what it does on solutions of moderate strength. As these latter (upward of 0.15 per cent.) are, perhaps, even greater than can occur in any condition leading to the presence of nucleo-albumin in the urine, apart from a pronounced vesical catarrh, which cannot mislead, heat becomes the most important mode of differentiating a nucleo-albuminuria from a serumuria.

From these results it would follow that the only reliable test for serum-albumin, and that freest from liability to error, is the old-fashioned one by ebullition. But, apart from commonly recognized fallacies attending its employment, easily overcome, at least two important sources of error, strikingly developed in these experiments, are likely to arise with urine containing more than traces of nucleo-albumin. Treatises on urine-testing advise in the employment of the heat-test, the precaution that, should no reaction be apparent immediately on ebullition, the tube be inspected after standing and cooling, for cloud or precipitate, which, not being found to be due to acid urates, indicates albumin or an albumose. Now, as heat is without precipitating effect upon a naturally acid, nucleo-albuminous urine, to which no further addition of acid has been made in process of testing, precipitation of the mucoid body, under the circumstances, would not occur; but if an acid be added in the application of the test, clouding will surely result as the urine cools, unless the acid have been added in too small an amount to overcome the neutralizing effects of the urinary salts. As related, the experiments with mucoid nucleo-albumin, artificially added in moderate amounts to urine, indicate that high heat tends to dissipate the cloud produced by acids, although, after forming, it will not entirely remove all its traces.

A second source of error is that relating to the presence of an excess of earthy phosphates in a decidedly nucleo-albuminous urine. In the various experiments made with mucoid-fortified urines, specimens of the morning-urine were selected. On two occasions specimens of urine voided during the day were also employed as diluents, which, like the morning-specimens, were found not to react to trichloracetic acid within five minutes' contact in the cold. With these latter, and with one specimen of morning-urine, although all were acid, a cloud occurred in the fortified nucleo-albuminous specimens in the heated upper portion, which was not dissipated by the addition of a few drops of 25 per cent. acetic acid to 10 c.c. of the boiling urine. Control-specimens (containing no nucleo-albumin) were found to also cloud on heating, but were readily cleared by a small amount of acid. This indicates

[1] THE MEDICAL NEWS, May 5, 1894. This plan was pursued in order that mingling of reagent and urine is avoided when the contact-method is employed, as is so likely to occur by application of the flame directly to the tube.

[2] Treatises on urinalysis, save Neubauer and Vogel, state that urinary *mucin* is precipitable by heat. Reisser, quoted by Neubauer and Vogel, found that ebullition does not change urine rich in nucleo-albumin (By rich, Reisser probably meant upward of 0.1 per cent., which is the greatest amount he at any time encountered.)

that the presence of nucleo-albumin in a urine rich in phosphates—a combination quite usual in the healthy in the day-urine, especially in that after food and exercise[1]—interferes with the solution of the precipitated phosphates by acetic acid, heat being coincidently applied to assist in the clearing of the mucoid reaction. This is an important point, ignorance of which has doubtless often given rise to error. It is of signal interest, as many urine-examinations, more especially those for life-insurance, are made of specimens voided under conditions giving rise to the presence of an excess of urinary mucin and of phosphates. But mucoid nucleo-albumin present in amount likely to originate error,[2] reacts to acetic or to citric acid, or to other of the vegetable acids, clouding more or less markedly at ordinary temperature, so that, by this means at least, the presence of excess is proved.[3] In testing for serum-albumin, should ebullition now not clear the acidulated urine, or at least not greatly diminish, the precipitate, the excess of earthy phosphates in a second portion of the urine should be removed in the usual manner, and heat later applied to the acid urine which has been first cleared by filtration.

It is of interest to here briefly detail the subsequent behavior of one of these albumin-free phosphatic urines to which about 0.2 per cent. of nucleo-albumin was first added, after the tendency to the marked precipitation of phosphates by heat was noted. The excess of the latter was precipitated by ammonia and removed by filtration. Later, the urine was rendered rather markedly acid and the nucleo-albumin thus thrown down removed. Repeated filtration gave a very clear solution, of a specific gravity of 1025. This, at ordinary temperature, still gave a cloud to acetic acid, but, however, tended to become quite clear on ebullition. Specimens gave a contact-cloud with nitric acid and a marked contact-ring with Millard's reagent; with trichloracetic acid the reaction was very decided; with metaphosphoric acid it appeared within a minute and was marked; with unacidulated picric-acid solution no immediate reaction occurred, but at the end of a minute a contact-haze was discernible, not increasing to an outspoken ring after standing for some time. With citrated picric-acid solution a fine, sharp ring was instantaneous. With all of these reagents, save metaphosphoric acid, the extent of reaction was diminished by the application of decided heat, although with trichloracetic acid this reduction in amount of response was less manifest than with the others. The reaction of this specimen to the various tests was most instructive, as it contained a very small amount of the mucoid body, calculated by similar response of other specimens, to which measured amounts were added, to be 0.02 per cent. or less. This specimen was of especial interest for study because of correspondence in point of response to several specimens of day-urine from healthy subjects I had recently examined.[1] These gave a pronounced acetic and citric acid mucoid cloud, and responded quite markedly to the delicate tests for albumin, gave a narrow cloud at or near the meeting-line with HNO_3 by the contact-method, but did not react to heat alone.

So far as I am aware, the valuable aid heat may render toward promoting a response, in the application of tests used by the contact-method, for the detection of serum-albumin is nowhere mentioned. As apparently heat also becomes a factor of importance in the separation of the so-called mucin-reaction from that due to serum-albumin its employment is most essential when there exists the slightest doubt as to differentiation. I have frequently been able to bring out a serum-albumin reaction with HNO_3 used by the contact-method, by placing the test-tube in hot water for some moments, which response otherwise was most tardy in appearing, if eventually noted at all. The use of heat in this way, rather than the application of the naked flame to the tube, is essential, in order that actual ebullition in the tube be not permitted, otherwise disturbance of the relative relation of reagent and urine would interfere with the occurrence of a sharp contact-ring.[2]

Although I think it may be confidently asserted that a reaction so induced, as with one also apparent without heat, if decidedly sharpened by suspension of the tube in the water-bath, is due to serum-albumin (or serum-globulin), yet, on the other hand, as heat will not entirely remove a mucoid response after it has once appeared, there can be no great certainty as to the absence of recognizable traces of serum-

[1] Exercise and the process of digestion tend to increase the amount of mucoid substance in the urine. From the merest trace, undetectable in the morning-urine, it may rise in amount sufficient to cause a reaction to the contact nitric-acid test. I have noted this in the urines of several healthy male adults since examining into this point.

[2] In the phosphatic urine mentioned, an amount of nucleo-albumin was added approximating 0.1 per cent.

[3] I have elsewhere dwelt upon the precautions necessary to insure a mucoid response with acetic acid, in urines with varying amounts of salts in which recognizable traces of mucoid nucleo-albumin are naturally present. The precipitating effect of acetic acid on urates must be borne in mind. The latter are differentiated by the fact that their precipitate is colored and has a characteristic microscopic appearance. They may be also recognized by the fact that a gentle heat, short of that necessary to diminish a mucinous reaction, clears the urate-precipitate. Dilution of the urine, before the addition of acetic acid, will also tend to obviate a urate-precipitate and to increase a mucoid one.

[1] Tested in all points similarly to the reinforced mucoid urine save as regards the dissolving effects of strong heat.

[2] By this method acid urates and a mucoid reaction are both prevented.

albumin in the presence of the nucleoid body. If smaller amounts of albumin are looked for, the same must be said of the use of the delicate tests, although it would appear that if these are applied[1] with reagent and urine at the boiling-point—a method, of course, impracticable in ordinary routine urine-testing—no mucoid reaction will occur so long as these are maintained at a high heat. Of the many delicate reagents, unacidulated solution of picric acid has the least reacting power to traces of nucleo-albumin. Decided preference should, therefore, be shown it over all of the others, if the employment of a refined test seems essential. Citrated or otherwise acidulated picric acid should never be employed. Especially should it be avoided in the quantitative estimation of albumin by Esbach's method.

A serious fallacy attending the influence of heat upon the trichloracetic-acid reaction in the experiments with nucleo albumin should be here mentioned. It tends to further illustrate forcibly the impracticable, extraordinary delicacy of this reagent as a precipitant of albumin, and its inutility for clinical purposes. In the course of the investigation a control-specimen of acid urine previously unfiltered, of that portion used for experiment which gave no reaction at ordinary temperature with trichloracetic acid until some minutes' contact,[2] was thoroughly boiled and filtered while hot. This was done with the object of obtaining a control-solution in all particulars similar (save as regards the presence of nucleo-albumin) to the fortified nucleo-albumin specimen. To my surprise, it was found that this boiled and subsequently but once filtered control-specimen reacted more markedly to trichloracetic acid than did the unboiled, unfiltered, original specimen. I then found that both cold and hot distilled water ran once or twice through specimens of all of the various makes of white filter-paper in my laboratory, gave either instantly or after the lapse of a few moments the contact white ring with trichloracetic acid.

I then procured specimens of the very best grades of fine filter-paper other than those which I had. It was thought that some of these would certainly not so react. Bearing as this matter does upon the subject of fallacies attending albumin-testing, the result is worth mention. The specimens, four in number, obtained from Messrs. Queen & Co., were marked *Swedish; French;* No. 390 and No. 589. They were of equal size, with a capacity of about 20 c.c. Two of each variety were used, one for hot distilled water, the other for distilled water at room-temperature; from 5 to 7 c.c. of each were passed through the filters in the usual manner several times. No pressure was exerted to force the water through. The distilled water in each instance was free from trace of cloud after filtration as before.[1] A slight contact white ring characteristic of traces of albumin occurred instantly with all of the specimens of distilled water filtered while hot, and tested in all save with the specimen of French paper while still warm. The albumin-reaction was quite decided with paper No. 390. With the cold, filtered, distilled water the reaction was instantaneous only in two, with but one filtration; in the others it appeared in from one-half to one minute. In all, the reaction became very much more decided on standing a short time; but although the use of the water-bath had no diminishing effect, heat did not seem to noticeably increase the reaction, as is the case with serum-albumin. A fine cloudy haze throughout the body of the tube was, however, developed by heat, indicating a precipitating effect of the trichloracetic acid, aided by heat, on the minute traces of albumin present. Experiments of various other sorts were tried with these solutions and trichloracetic acid, which, though interesting, cannot be detailed here. Millard's reagent, plain or citrated picric acid solution, and the reagents of the tartrated mercuric chlorid were found to give no indication of reaction, even after standing in contact for some time.

Millard, a number of years ago, called attention to the fact that the coarse French gray filter-paper, which contains a great deal of cellulose or vegetable albumin, would yield sufficient to react to his reagent. This I long ago confirmed, finding that several of the delicate tests reacted to distilled water passed through the gray paper.[2] Trials made at that time with the white Swedish, French, and German makes, and the same tests, were resultless, so that it had not been suspected that a fallacy from this source, with a good quality of filter, existed.

To remove the traces of nucleo-albumin from suspension, it was necessary to repeatedly filter its menstruum; from three to six papers were always employed, all of which probably contributed their quota of albumin to the filtrate, which would increase the amount of albumin recognizable by trichloracetic acid uninfluenced by heat.

Trichloracetic acid as a reagent for the detection of albumin is of such exceeding delicacy that, though evidently of little practical utility for clinical purposes, it apparently may be utilized to demonstrate, without need for concentration of urine, the existence of a constant normal albumin-trace. A phys-

[1] Excepting metaphosphoric acid.

[2] And then but a very fine white ring, showing rather less than the ordinary normal traces of albumin.

[1] For the sake of exactness, a control unfiltered specimen of distilled water was also tested with trichloracetic acid. As might be expected, it gave no reaction.

[2] Trichloracetic acid had not then been proposed as a test for albumin, and thus was not used.

iologic albuminuria asserted to exist by Leube,[1] Fürbringer,[3] Kleudgen,[3] Senator,[4] Chateaubourg,[5] Capitan,[6] Posner,[7] and others, has been as strongly questioned by v. Noorden,[8] Millard,[9] Lecorché and Talamon,[10] and many others. The confines of this paper do not admit of even a cursory survey of existing data for or against this important question; the subject is one that requires much space for its consideration and will receive attention subsequently. Suffice it here to state that much of the work was done with concentrated urines, and the question of the frequent presence normally of extra-renal mucoid nucleo-albumin was often altogether ignored by those favoring the existence of a physiologic albuminuria. Leaving out of consideration the frequent high percentage of marked albuminurics among the apparently healthy, to be accounted for as a result of digestive derangements, circulatory weakness and the like, not omitting a latent nephritis, the fact that many of the experimenters in the field of physiologic albuminuria, who confidently hold to the existence of a normal minute albuminuria, fail to consider the presence of nucleo-albumin as a complicating factor, has thrown much doubt upon the results arrived at. Still regarding albuminous bodies other than serum-albumin which may be present in the urine and are calculated to mislead, the experiments of many observers[11] have at least shown that at times no reaction may be obtained with such delicate reagents as Tanret's and Millard's; and Leube failed to get an albumin-response in some entirely healthy urines which had been subjected to much concentration. If the experiments which I have detailed with the reactions of mucoid nucleo-albumin to certain of the tests for albumin represent those obtainable when this body is present in traces in healthy urine, as I think there can be little doubt, then it can be proved that Posner is right in asserting that all urines contain demonstrable traces of albumin, and that a physiologic constant minute albuminuria exists, an albuminuria which apparently is not due entirely to the presence of a mucoid body, although it may perhaps still be accidental or contingent, and not arising from the blood-serum of the renal vessels.

In the paper on fallacies attending the employment of delicate tests for albumin it was stated that in a series of 105 urines from presumably healthy male adults, 102 gave at ordinary temperatures a contact-reaction characteristic of albumin within five minutes, and that the remaining three also readily reacted within this time on the employment of heat, showing a contact white ring of one or more lines in depth. The reaction in the 102, further tested by heat, was apparently increased.[1]

Since the series of 105 consecutive urine-examinations, in all of which the specimens reacted, as stated, to trichloracetic acid, I have examined a series of 35 morning-specimens from presumably healthy males in the prime of life, none of whom contributed any of the preceding specimens examined.[2] With the exception of but 2, applying the technique detailed in the other paper, without the aid of heat, a reaction was noted in all[3] within five minutes. In nearly all of these it was quite marked in this time. In the remaining 2 a contact-reaction was noted within ten minutes. In 13 the reaction was instantaneous, but in 2 only was it immediately very decided, and these were found to be examples of markedly albuminous urine reacting to coarse tests. In 6 only of the 33 could the reaction be termed slight at five minutes' contact.

The effect of heat upon all of the specimens which had reacted before its application was carefully studied, and was noted to vary somewhat with different specimens. In some it very markedly and promptly intensified the sharpness and depth of the contact-ring, which had not been very decided before the use of the bath. With 4 the effect of heat was negative, viewing the tube after some minutes' exposure to the bath. The contact-cloud remained as before, deepening, however, quite markedly, as was the case with all, after cooling and standing. It was certain that in all heat developed earlier a reaction which, without heat, was several minutes in becoming well-defined. In one of the 2 in which no response occurred in the cold until after five

1 As the influence of heat upon a slight mucoid reaction was not then understood, less attention was paid to long contact in hot water; nor was the latter always maintained at the boiling-point, it being more especially desired to differentiate as to urates rather than as to varieties of albumin. The nucleo-albumin experiments show that unless the heat be decided, and the amount of nucleo-albumin present small, the soluble effect of the former is not apparent. In fact, although lessening of reaction with heat was quite constant with traces of nucleo-albumin, it was not always so to the same degree. It was common, too, for a mucoid response to become again decided as the temperature of the water fell from boiling-point to a degree of heat still decided to the finger.

2 Thirty-one of these 35 were collected for me by my friend Dr G. M. Gould, to whom I am under warm obligations for them.

3 In the specimens of the 105 urines less than 10 of the number had been filtered before testing. In none of the present 35 was filtration practised. The portion to be tested was always taken from the upper stratum, after subsidence of any mucous cloud in suspension.

minutes' contact, it was noted that heat within a moment or so produced a contact-cloud of a depth of three or four lines, which cloud supplanted the slight, although more sharply defined, white ring evident without heat. The urine above in the tube also subjected to the bath became hazy. On inspecting the cooled tube subsequent to the use of heat, after it had been standing for some time, a sharply defined contact-ring was again noted of a much greater extent than at first, with a deep cloud above of some lines in depth.

One fact seems to me certain, developed by the examination of a series of nearly 150 specimens of urine from young male adults, the majority of whom are apparently in robust health, and none of whom had been regarded as renal suspects, that, excluding the 22 marked albuminurics, whatever the nature of the albuminous body reacting, a response may be obtained in any specimens of all urines of the healthy by the intelligent employment of trichloracetic acid. This response may not occur instantly, but usually develops within a few moments, and may be brought out in any instance by the use of heat in the manner described.

SYPHILIS OF THE NERVOUS SYSTEM.

BY JOHN FORD BARBOUR, M.D.,
OF LOUISVILLE, KY.;
NEUROLOGIST TO THE LOUISVILLE CITY HOSPITAL.

VIRCHOW has said that the cerebral manifestations of syphilis are as manifold as the cutaneous, and that the spinal manifestations are as manifold as the cerebral.

The early recognition of the essential nature of these various manifestations is of the utmost importance, for nowhere else in the whole range of therapeutics does prompt and vigorous treatment produce such wonderful effects as in syphilis of the nervous system.

The lesions produced by syphilis are of three kinds: first, the gumma; second, syphilitic endarteritis; third, the diffuse syphilosis of Heubner. In addition to the symptoms produced by these lesions, which act mainly in a mechanical way, the toxin of syphilis, under conditions which we do not at all understand, may directly attack the protoplasm of the nerve-cells or the axis-cylinders, which are composed of the same substance, as in paretic dementia and locomotor ataxia. This view finds support in the fact that central paralyses and psychoses may be caused by the toxins of other infectious diseases. Such occurrences have been reported as sequelæ of influenza, typhoid fever, measles, pneumonia, rheumatism, diphtheria, scarlet fever, and erysipelas. In these there can be no question of an extra-neural lesion, as in most cases of nervous syphilis; the toxins must have acted directly upon the nervous protoplasm, and any other changes found must have been secondary or merely coincident. We know that the toxins of various germs undergo great variation after prolonged cultivation or passage through the bodies of various animals. To mention a single instance of this, the virus of hydrophobia increases in virulence when passed through guinea-pigs, but diminishes in virulence when passed through monkeys. Why may we not reasonably suppose that the virus of syphilis, after prolonged cultivation in the body, may undergo such changes that, instead of producing its customary lesions, it acquires the power of directly attacking the nervous protoplasm? That such changes occur in the toxins of other infectious diseases is plainly shown by the fact that the central paralyses mentioned do not occur until long after the primary symptoms of infection have disappeared. In typhoid fever, for instance, these paralyses occur during convalescence, some eight or ten weeks after the primary infection.

When and by whom was the canon of syphilitic lesions declared closed, and who can say, "Syphilis can only produce a certain number of lesions of the nervous system; I deny that any other changes are specific in character?" To claim, as is so often done, that syphilis merely predisposes to paretic dementia and locomotor ataxia is, as Strümpell has well said, simply a meaningless expression. It is as if someone should say, "Typhoid fever can only produce one characteristic lesion, which consists in certain changes in Peyer's patches. If central paralyses occur during its course, I deny that these are directly due to the typhoid fever, though it may act as a predisposing cause"—and so on through the list of infectious diseases. The fallacy of such reasoning is apparent.

Syphilis during its various grades of culture in the human body shows a preference first for one and then for another of the tissues—attacks now the skin, now the mucous membranes, now the bones, then the meninges of the brain or cord, or the walls of the bloodvessels, etc. It is only necessary to add another category of specific lesions, viz., those cases in which it attacks the nervous tissue proper.

We might class the various forms of nervous syphilis under the following heads:

1. Gummatous.
2. Vascular.
3. Interstitial.
4. Parenchymatous.

Gummous syphilis produces, of course, merely the symptoms of tumor. If the gumma be in the motor area, there will be epileptiform attacks or paralysis, according to the degree of pressure; if it press upon the cord, a compression myelitis will

occur; if it impinge upon a nerve, a neuritis will result, and so on.

In vascular syphilis the cerebral symptoms are those of apoplexy, from rupture of a bloodvessel, and thrombosis with its attendant cerebral softening, which is brought about by the narrowing of the lumen of the vessels and roughening of the internal coat from endarteritis. Cases of acute transverse myelitis, following syphilis, probably arise in the same way; while in chronic myelitis there is a slow cutting off of the blood-supply, but no formation of a thrombus.

The interstitial form is attended by an increase in the connective tissue, its organization into bands of sclerotic tissue, the occurrence of a syphilitic exudate, and so on. This gives rise to meningitis, which may extend into the cord and produce a meningo-myelitis, or it may produce an interstitial encephalitis.

Under the head of parenchymatous syphilis are to be included the syphilitic psychoses, syphilitic neurasthenia, paretic dementia, locomotor ataxia, progressive bulbar paralysis, progressive muscular atrophy, and amyotrophic lateral sclerosis.

The psychoses are placed under this head for the reason that similar affections are often produced by the toxins of other infectious diseases, notably by that of influenza, which must act directly upon the nerve-substance; the symptoms are too widespread to be due to gumma; the complete recovery of many of these cases would seem to shut out interstitial and vascular changes, for these leave permanent results.

The propriety of placing paretic dementia under this head will, no doubt, be questioned, for it has been much discussed whether the primary changes in this disease are interstitial or parenchymatous. The weight of authority seems to be in favor of the latter view. Hirt states that "this view, according to which the atrophy is the primary process, is in all probability correct, though it is still combated by many authorities (Mendel), who look upon the death of the nerve-fibers as the secondary, upon the increase of the connective tissue, the thickening of the vessel-walls, and the appearance of spider-cells as the primary process."

Ziegler says, in his *Lehrbuch der allgemeinen Pathologische Anatomie und Pathogenese:* "The disturbed nutrition and the degeneration of the ganglion-cells and nerve-fibers are the important matters; while the inflammatory infiltration and the increase in the connective tissue have no real significance as far as the symptoms of the disease are concerned."

And Strümpell remarks: "We ourselves, with Tuczek, Wernicke, and others, are much more inclined to the theory that we have to do mainly with a primary process of degenerative atrophy of the nerve-fibers and nerve-cells, to which the increase of the connective tissue is only a secondary addition."

Finally, the influence of chronic alcoholism in the production of this disease, upon which Magnan lays such stress, would seem to sustain this view, as alcohol is a parenchymatous poison.

Precisely the same discussion has been waged concerning the primary lesion in locomotor ataxia, some holding that the disease first causes an atrophy of the axis-cylinders of the affected nerve-fibers, which is followed by a sclerotic process, while others maintain the opposite view. The trend of opinion at present seems to be toward the first view.

The same considerations apply, of course, to the question of the intimate nature of syphilitic neuritis.

The question of diagnosis brings up Wood's famous therapeutic test, viz.: "The vast majority of persons who are free from syphilitic affection cannot take doses of over ten grains of potassium iodid three times a day without the production of iodism, except as the result of the habitual use of the remedy."

The active discussion which the announcement of this rule brought forth served to arouse the attention of the entire profession in America upon this point. So many cases of tolerance of iodids in large doses in which there was no suspicion of syphilis were found, on the one hand, and so many undoubted syphilitics who could not tolerate thirty grains *per diem*, on the other hand, that I believe that I am stating the general opinion on the subject in saying that the word "vast" should be stricken out.

The prognosis is determined by two considerations—the length of time the disease has lasted and the nature of the lesion. Many physicians have the idea that because the disease is syphilitic the prognosis is invariably good; but one should consider how much of the new tissue is syphilitic, and therefore removable by treatment, and how much is extra syphilitic and permanent. Specific remedies will cause a gumma to disappear, but they cannot dissipate the connective-tissue growth which the presence of the gumma has called forth. Victor Horsley has gone so far as to advise the surgical removal of well localizable gummata.

The prognosis seems to be best in the gummatous form of nervous syphilis, for the reason probably that this soonest of all produces marked symptoms which call attention to its presence. If a man suddenly develops epileptiform attacks or paralysis, he will at once consult a physician, and if the cause is recognized the prospect of permanent and entire relief is good. But a patient might suffer for months with the much more vague symptoms of syphilitic endarteritis without consulting a physician until the

occurrence of thrombosis would place him beyond all hope.

The prognosis is next best in parenchymatous syphilis. Out of twenty-three cases of syphilitic psychoses collected by Wood in his monograph there were twenty-one recoveries, one apparent recovery, and one relapse, which resisted all specific treatment. Now, it is entirely out of the question that these psychoses should have been produced by gummata, or even by multiple gummata, for the symptoms were too widespread, involving the entire cortex. They must, then, according to prevailing ideas concerning syphilitic lesions, have been due to interstitial or arterial changes. But if such changes had progressed so far as to produce marked psychoses, could these patients have made a complete recovery? Is there any evidence that specific treatment can restore the lumen of a vessel obliterated by syphilitic endarteritis or remove interstitial connective tissue? Is the sclerotic tissue in these cases in any sense specific, does it differ in anywise from other sclerotic tissue, is it any more susceptible of removal by treatment when it has once formed? Is it not precisely in those cases in which the lesion is interstitial or arterial that treatment does least good or entirely fails?

If we admit, on the other hand, that there is a parenchymatous form of nervous syphilis; that the cells of the cortex have a wonderful power of resistance to poisons, as is shown in the prolonged abuse of alcohol and opium; that their action may be perverted by various poisons for years, and yet when the poison is removed they will entirely recover their functions; that when they are overcome by the poison and die, their place is filled in by connective tissue—admitting these things, we have, it seems to me, a satisfactory explanation of the occurrence of these psychoses and recovery from them.

Even in syphilitic tabes, according to Erb's statistics, the prognosis is fairly good, if the secondary sclerotic process has not advanced too far.

Gowers has announced an exceedingly important fact bearing upon the treatment of syphilis, viz.: that the germs rapidly acquire a tolerance of the iodid, which they as rapidly lose. Hence the best results are gotten by administering iodid for a period of six weeks, and discontinuing it for a like period. The continuous use of the iodid defeats its object.

Certainly there are few American physicians who will agree with Gowers when he says: "I believe that this dose of iodid (grs. xv t. i d.) is adequate, and will do all that can be done in the course of four to six weeks. It is better not to give larger doses, because coagulation of the blood plays a part in the mechanism of destruction, and large doses of the iodid, as the history of aneurism has taught us, increase the tendency of the blood to clot." The use of massive doses of the iodid in these conditions originated in the United States, and certainly every one has seen cases in which fifteen grains three times a day would not affect the condition, but which improved rapidly under several hundred grains *per diem*.

In choosing between the iodid and mercury, the greater rapidity with which the latter acts should be borne in mind. Nervous syphilis is so treacherous a disease, the lightning is so apt to strike one out of a clear sky, that it is certainly wise to lose no time, but to begin treatment with a thorough course of mercurial inunction. This method of administering mercury is far preferable to any other in this class of cases.

The importance of varying and individualizing the treatment should be remembered. When the case has come to a standstill under the ordinary remedies, undoubted good is done by the vegetable alteratives.

A very important matter is that of prophylaxis. In how far is nervous syphilis preventable? This is classed among the tertiary symptoms. The following are Fournier's latest statistics upon this subject. Among 1703 cases tertiary symptoms appeared in the following numbers, their previous treatment being known:

	Cases.
No treatment	217
Short treatment (under one year)	1162
Moderate treatment (from one to two years)	265
Long treatment (over two years)	53
Treatment exceeding three years	6
	1703

"We find, then," says Fournier, "that among 1703 cases there were 59 in which tertiary symptoms appeared after, and in spite of a vigorous and, we may believe, sufficient treatment; while there were 1644 cases after an abbreviated, insufficient, or expectant treatment."

Again, in 100 cases of cerebral syphilis, Fournier found 5 which had received vigorous and prolonged treatment with mercury; in 6 cases the treatment was of a moderate but doubtless insufficient duration; 10 patients were only treated from 7 to 18 months, and 70 from 1 to 6 months; in 4 there had been no treatment; and 5 had taken nothing but the iodid.

Fournier draws the following conclusions from these facts: "Out of 100 patients, 5 had received a thorough and prolonged treatment, as against 95 who had received some other treatment, or none at all. So, then, syphilis of the brain is nineteen times rarer after prolonged treatment."

As to what proportion of cases present nervous syphilis, Fournier states that among 3429 cases, 1085 were instances of syphilis of the nervous system.

In discussing these statistics before the Wiener Medizinisches Doktoren-Collegium, November 6, 1893, Dr. Finger remarked that at the Congress in 1889, when Fournier presented these statistics, other authors, Mauriac, Haslund, Leloir, reported very similar results. As to syphilis of the nervous system, it should not be overlooked that Fournier considers tabes, progressive paralysis, and the muscular atrophies as syphilitic.

The object of therapy in syphilis is to prevent the appearance of tertiary phenomena. It is well known that the frequency of the tertiary symptoms is in inverse ratio to the lightness of the secondary stage, and this is for the reason that we adapt the symptomatic treatment to the light, secondary stage. The symptomatic treatment is a defensive procedure; it deals with the present symptoms. A portion of the virus remains behind, and, thanks to the treatment, has time to increase and make a new attack. This again is dealt with defensively, and so the scene repeats itself over and over. It is much more logical constantly to attack the virus. But as the mercury accumulates in the system and the latter becomes accustomed to the poison, there should be intermissions in the treatment. Finger had used the prolonged treatment for ten years, and had very seldom seen tertiary symptoms in his patients or hereditary syphilis in their children (*Deutsche med. Zeit.*, 1893, No. 95).

As tertiary symptoms have occurred as long as fifty-five years after primary infection, one had best give these patients a life-sentence, and tell them that they must keep up treatment the rest of their lives. Let them take six weeks' courses four times a year. The physician should lose no opportunity of dangling Damocles' sword of nervous syphilis over the heads of these patients. It is amazing what perfect indifference many of them show and how difficult it is to make them keep up treatment.

In conclusion, I wish to report briefly some of the cases of syphilis of the nervous system which have come under my notice and which present points of interest:

CASE I.—This patient had progressive aphasia from a syphilitic lesion. There were no other symptoms. He lost his parts of speech in regular order, following exactly Ribot's law; first proper names went, then adjectives, and so on. Finally his whole vocabulary was reduced to interjections, expletives and oaths. He recovered his parts of speech in the inverse order—in the order in which evolutionists say that mankind acquired them. This case serves to show what a deep, fundamental need of our nature profanity supplies. The lesion was evidently a gumma exactly limited to the speech-center.

CASE II.—I was called in consultation to see a policeman. He had complained of headache for a day or two, and then in a few hours became comatose. When I saw him his breathing was slow and stertorous, pupils uneven, pulse full and labored, and there was left hemiplegia. I felt strongly inclined to bleed him. A history of syphilis being obtained, he was ordered mercurial inunctions, to be followed by increasing doses of the iodid. In six weeks there was no trace of the hemiplegia left. This was probably one of those singular cases of sudden congestion about a gumma, like the apoplectiform attacks of multiple sclerosis.

This man now presents uneven pupils, hesitancy in his speech, failure of memory, and fibrillary tremor of the lips; but in spite of all I can do, it is impossible to get him to keep up his treatment. When he has his next attack I shall certainly bleed him.

CASE III.—G. X., a Portuguese sailor, was an inmate of the Louisville City Hospital for about a year and a half. No history could be gotten. He had all the signs of cerebellar involvement, strabismus, diplopia, vomiting, and titubation. His gait was like that of a drunken sailor on shore after a long sea-voyage. He was given the benefit of the the doubt and placed upon specific treatment, taking at one time as high as 200 grs. of the iodid at a dose. This produced rapid improvement up to a certain point, but beyond this it was impossible to benefit him by any amount of treatment. Probably what had happened was that the syphilitic portion of the cerebellar gumma had been absorbed, leaving behind a considerable mass of scar-tissue.

CASE IV.—J. H. thirty-four years of age, suddenly developed violent epileptiform attacks. They came quite close together, and in the intervals between them he complained greatly of headache and insomnia and was very confused mentally. I saw him about an hour after the third attack, which came within a week of the first one. He was sitting stupidly upon the side of the bed, unable to recognize anyone. In a case of this sort it is hardly necessary to ask a single question. He was put upon treatment at once and made a complete recovery, never having another attack. This case shows how favorable the prognosis of gummatous syphilis is *sometimes*.

CASE V.—L. F., a lawyer, aged forty five, noticed one day that his left foot dragged a little and he had difficulty in raising the toe of his shoe from the ground. By the next morning the weakness had extended to the arm. I saw him the afternoon of the same day, when the left side of his face was somewhat involved. On inquiry he admitted that he had had a sore on his penis some twenty years before, which had healed up after six weeks of treatment. Evidently there was a gumma situated near the median line on the right side and spreading down over the motor tract of the right hemishpere. Remembering my experience with Case IV, I gave a favorable prognosis. The patient improved so rapidly under mercurial inunctions that he was able to leave for Atlanta in a week, where he died about two months afterward. Whether the treatment was not properly carried out, or whether it was one of those singular cases which prove utterly rebellious to treatment, I am unable to say.

CASE VI.—J. T. entered the Louisville City

Hospital on Wednesday morning in a state of great mental confusion, and unable to give any account of himself. That night he became maniacal and had to be strapped in bed. I saw him Thursday morning. He was comatose and had left hemiplegia. There were characteristic scars over the tibia. On making firm pressure over the left tibia the patient drew up his right leg and made a defensive movement like a Goltz frog. That night he was so wild that he could hardly be kept in bed. He died on the next morning. A post-mortem was held that afternoon. We found softening of all that part of the right hemisphere supplied by the Sylvian artery, which might well be called the motor artery. The arteries at the base were grayish in color, resistant to touch, and patulous. The caliber of the Sylvian artery was reduced to the size of a knitting-needle, its inner coat was roughened, and it was completely obstructed by a thrombus.

CASE VII.—P. S., foreman of a bridge-company, forty years of age, entered my office one day with marked ptosis. I asked him at once, "How long is it since you have had syphilis?" "Twenty years," he responded, greatly astounded at the omniscience of the medical profession. Ptosis in an adult is a symptom which points very strongly to nervous syphilis. The patient dated his present trouble from a blow received upon the head about three months before. It has been very much debated whether injuries to the head have any localizing influence in such cases. He had had very little treatment at the time of the initial lesion; there were no secondary manifestations. Recovery followed.

CASE VIII.—Mrs. S., a widow, twenty-nine years old, had suffered from constant headache for nine weeks, for which she had received hypodermatic injections of morphin and ten-grain doses of potassium bromid, that panacea for all diseases of the nervous system. When I saw her she had reached that stage when she could neither sleep nor remain awake. About three weeks before, she had had an attack in which she fell to the floor and lay unconscious for perhaps twenty minutes, when her daughter came in and helped her to bed. She knew nothing more then for twelve hours. There were nocturnal exacerbations of the headache. Examination revealed the presence of a tumor in the forehead about the size of half a pea, which was exquisitely sensitive to pressure. She had lost thirty or forty pounds in weight and could eat nothing. This case would probably have ended fatally in a short time if its nature had not been recognized. After forty-eight hours of vigorous treatment the headache showed signs of yielding, and has since entirely disappeared. This was a genuine case of "syphilis insontium," as the woman was so ignorant that she did not know the meaning of the word syphilis. Her husband had died about three years before of a "relapse of the measles," at Hot Springs.

I debated some time whether or not I should inform her of the true nature of her headache, and finally concluded that it was best to do so, as she might fall into ignorant hands again. She gradually recalled certain significant facts. She had been treated once for a mysterious uterine disease; her husband held long secret confabs with the doctor in the hall. There had been a sore at the corner of her husband's mouth, which the doctor had warned her she must be careful not to touch in case she had any sores upon her hands. She has two children with Hutchinsonian teeth. Subsequently she developed syphilitic iritis, which yielded promptly to treatment.

CASE IX.—Dr. Ap. Morgan Vance referred to me a little girl, two years old. The mother gave the history of having had two children stillborn at full term, and one miscarriage. The child had marked spastic paraplegia, with greatly exaggerated tendon-reflexes, and Hutchinsonian teeth, and was very backward in mental development. She could not crawl upon the floor, and her vocabulary consisted of three or four words. The treatment consisted in mercurial inunction, prolonged warm baths, and galvanism to the spine. In eight weeks there was marked improvement in the symptoms, the mental change being especially noticeable. She has continued to improve steadily since then, and is learning to walk and to talk. Another similar case sent me by Dr. Vance has shown improvement under the same treatment.

CASE X.—J. K., forty-seven years of age, gave the history of a chancre some twenty years ago, for which he took treatment until the sore healed. No secondary symptoms followed. About three years ago he began to notice that it was difficult for him to walk at night, so that he stopped going out after dark. I saw him several months after this, when he presented the following symptoms:

Argyll-Robertson pupils, girdle-sensation, vesical disturbance, swaying with the eyes closed, anesthesia of the lower extremities to a slight degree, ataxic gait, and exaggerated knee-jerk. This case corresponds to Erb's type of spinal syphilis. No improvement followed under potassium iodid carried up to 600 grs. per diem, and there were no symptoms of iodism. There was some improvement under mercurial inunction.

CASE XI.—I was called to the City Hospital one night to see a woman who had suddenly developed acute mania. She was strapped in bed with her hands in the muff, and was filled with a burning desire to cut somebody's heart out. She quieted down under a large dose of chloral. The diagnosis of cerebral syphilis was easily made, as she was an "old rounder" who had formerly been treated for a chancre. Vigorous specific treatment was at once instituted, and she made a prompt and complete recovery. No other cause but syphilis could be discovered for the attack. It seems hardly possible that it could have been due to grumma, to interstitial syphilis, or to syphilitic arteritis. Yet the ready response to treatment showed that it was specific in nature.

CASE XII.—One of the internes at the City Hospital called my attention to a man who was sitting half asleep upon the edge of his cot. When aroused he stated that he could not remain awake for five minutes at a time, neither could he sleep soundly. At night he was in a condition bordering upon mild delirium, and showed a disposition to get out of

bed and wander about the ward. This state is well nigh pathognonomic of cerebral syphilis, which may produce the condition of extreme sleepiness or extreme wakefulness. The patient made a speedy recovery.

Case XIII.—J. D., a laborer in the glassworks in New Albany, Ind., developed symptoms of locomotor ataxia about three years after the initial lesion. The case progressed so rapidly that when I saw him, twelve months afterward, he was far along in the third stage, with complete optic atrophy, loss of control of the sphincters, etc. He died about two months afterward. The nature of his disease had not been recognized, and he had received no specific treatment. He stated that the room in which he worked at the glassworks was so full of gas that it was no unusual thing for a man to be overcome by it and fall unconscious. What effect this may have had in the development of his spinal lesion it is impossible to say.

Case XIV.—W. T., fifty-one years of age, was entered in the case-book at the City Hospital as a case of locomotor ataxia, the simple definition for this disease in vogue at that institution at that time being, "a disease of the spinal cord, causing disturbance of gait." The man really had paretic dementia of syphilitic origin, with descending degeneration of the crossed pyramidal tracts, producing spastic paraplegia.

There were delusions of grandeur. He promised a horse and buggy to each of the internes. Besides this, he had uneven pupils, fibrillary tremor of the lips, and other signs of paretic dementia. He left the City Hospital and wandered about the streets for several days, sleeping in outhouses. The last time I saw him he was sitting upon the curbstone, with his feet in the gutter. He hailed me cheerfully, and said, "I'm goin' to send you that horse and buggy next week, shore."

215 W. Chestnut Street.

A TREATMENT OF TYPHOID FEVER.[1]

By SAMUEL A. FISK, A.M., M.D.,
of Denver, Colorado.

In these days, when the Brand treatment of typhoid fever is the only one receiving any consideration, and the discussion in medical circles, with reference to the treatment of this disease, is confined to a consideration of hydrotherapy, it seems a little presumptuous for one to come forward with another presentation of the subject. My excuse must be that an observation of the results obtained by another method of procedure, extending over a number of years past, has led me to the conclusion that there is in this method something that is, at least, worthy of consideration. I am duly sensible that the presentation that I can give of my subject, at this time, is not based upon such a series of cases so scientifically conducted as to carry the fullest conviction, and my regret is that the hospital-services of a somewhat new community do not afford the same opportunities for careful and scientific investigation as exist in older and more settled centers. That my opportunities for observation have not been altogether limited will be illustrated by a study of the mortality-tables of Denver and of other cities.

In his recent report on typhoid fever, Professor Osler states that for the years from 1888 to 1892, inclusive, Baltimore gives a yearly average of 229 fatal cases; Boston a yearly average of 160.4 fatal cases; New York a yearly average of 379.4 fatal cases; and Philadelphia a yearly average of 661.8, while Denver for the same length of time gives a yearly average of 149.6.

My observation of typhoid fever, both in private practice and in hospital-service, during these years has brought me to the belief that the line of treatment which I, in common with a few others in Denver, have followed was productive not only of a small rate of mortality, the exact ratio of which I unfortunately cannot give, but also of a mild run of the fever, a minimum of complications, and a very decided diminution in the duration of the attack.

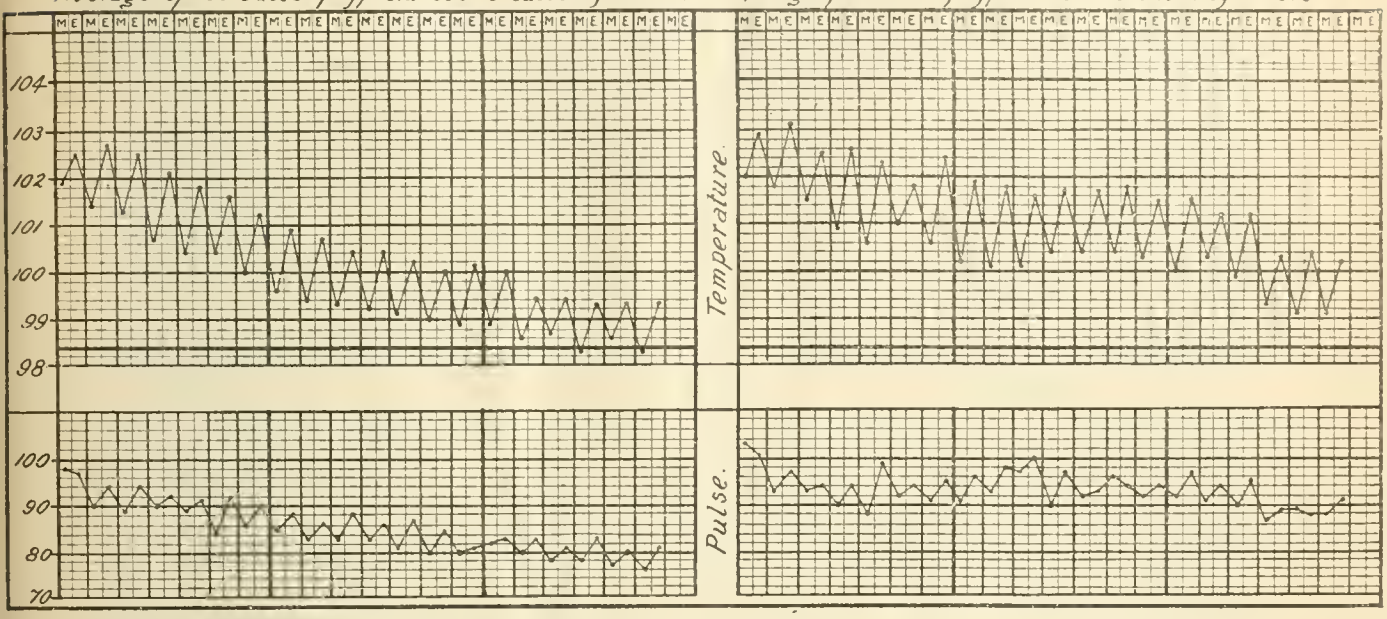
I beg to base my presentation of the subject on the accompanying charts. The first is a composite of thirty cases of typhoid fever, temperature and pulse occurring under my own observation; the second is a composite of thirty cases, temperature and pulse, occurring in the services of other practitioners at the same hospital with myself, and I wish to state that the composite is introduced with the consent of my confrères and solely for the purpose of illustrating my subject. The third chart is taken from the article by Professor William Pepper in his recent American text-book of the *Theory and Practice of Medicine*, and is introduced as a typical chart of typhoid fever. The cases selected to make up the composite are assumed to be average cases scattered over three seasons and are not taken with any view to influencing unduly the result. The composite in each case is obtained by adding the thirty morning temperatures on the day of admission and dividing by thirty and so obtaining an average. The same is done with all the other morning and evening temperatures and pulse-rates. For the accuracy and care with which this has been done I am indebted to my friend Dr. C. D. Nelson, a recent graduate of the Harvard Medical School. The composites would seem to indicate that the average case, in hospital-service, comes under observation with us, as with Professor Osler, at about the end of the first week. Comparing, then, the composite of the thirty cases of my confrères who did not use the Brand treatment, with the typical chart

[1] Read before the Association of American Physicians, Washington, May 29, 1894.

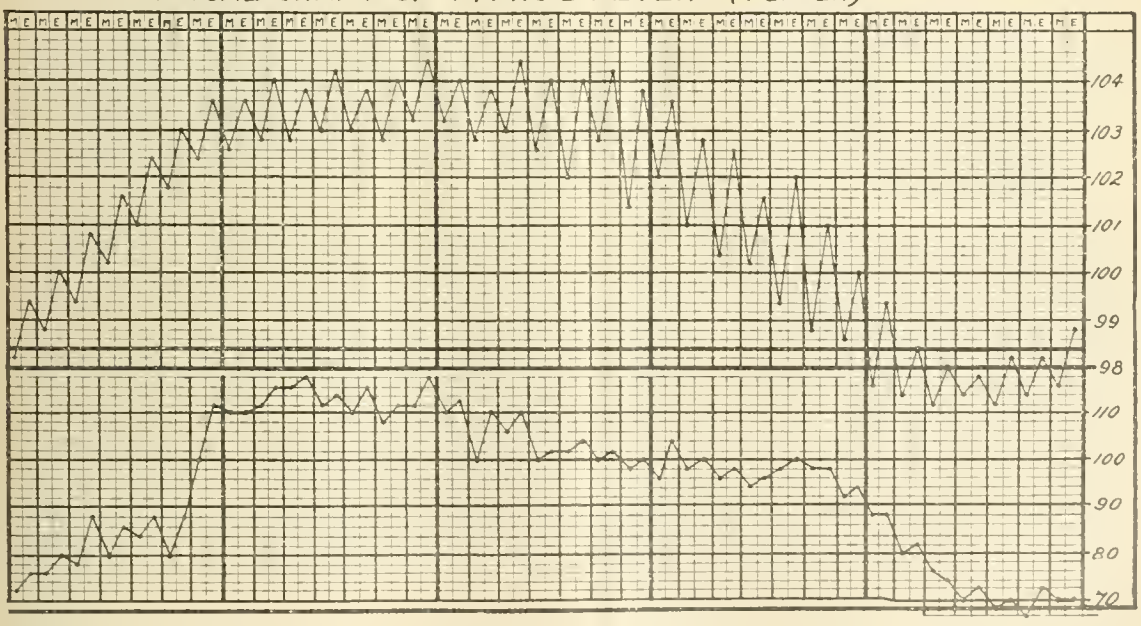
of Pepper, it would seem that the average case of typhoid in Denver is a milder one than prevails in Eastern cities. But our mortality, averaging 1.5 deaths to every 1000 of population, indicates that it is not without danger even here. Even allowing

late Dr. James H. Hutchinson, has justly remarked that "medicines are, however, by no means useless in the treatment of typhoid fever. There is no question that the disease is not only generally conducted to a favorable issue, but that its duration is often

COMPARATIVE CHART



TYPICAL CHART OF TYPHOID FEVER (PEPPER)



that the prevalent type is milder with us than elsewhere, which I am in doubt about, it nevertheless seems, from the composite of my own thirty cases, as though treatment had a decided influence in affecting the type. So careful an observer as the

materially shortened by their judicious use." My own composite would seem to show the justice of this remark. I myself was greatly surprised to see the result of the composite. The steady decline of the temperature from the very outset and a coinci-

dent decline of the pulse-rate are marked. It does not show the ordinary stage of *fastigium* with its two weeks' duration and then the decline by *lysis*. It goes without saying that with this decline in temperature and pulse there is a steady improvement in all the symptoms. The patient, of course, loses flesh and strength. He is not likely to suffer from delirium, from tympanites, from dryness of the tongue, from sordes, or from tremor or any marked nervous symptoms. I might say that I never, or almost never, see a dry tongue, and such delirium as I witness is likely to be mild in character and confined to the night hours of the first few days, and generally disappears in a short time with the subsidence of the headache. In the main the treatment is as follows:

Absolute rest. If the patient is seen early in the attack, as gauged somewhat by the absence of rose-spots and other constitutional symptoms, I give five grains of calomel at night and follow it with a Seidlitz powder, or some saline, in the morning, and this is the only administration of calomel during the progress of the disease. I then put the patient on an absolute milk-diet, giving a tumblerful every three hours. As a rule, I am not influenced by the patient's ideas that it is impossible to take milk, but determine that by my own observation. When I find this to be true, I have the milk peptonized and sometimes change to buttermilk. Extractive matters in the way of broths and extracts are not used, as they always seem to me to be harmful.

The turpentine-mixture used is becoming well-known in our hospitals and is meeting with great favor. It is constituted as follows:

R.—Ol. terebinthinæ . . . . . f℥j
Ol. ricini . . . . . f℥j.
Bismuthi subnitratis . . . . ℥iv.
Mucil. acaciæ . . . q s. ad f℥iv.—M.

This must be shaken well and a teaspoonful given in a little water twenty minutes after the goblet of milk. The turpentine in this formula seems to be sufficient to keep the tongue moist and to stimulate the bowels; the castor-oil keeps up the secretions, and the bismuth acts, as is well-known, as a dressing to the inflamed mucous surface; the last also has a constipating effect, which is overcome by the administration of castor-oil, from a dessertspoonful to a tablespoonful every other morning. For the restlessness of the first few days, which is especially marked at night, I use either five grains of Dover's powder, to be repeated once or twice during the night, or ten drops of McMunn's elixir of opium, to be repeated once or twice if needed. Water, iced if preferred, is given freely, and lemonade, not too sweet, is allowed, but not to conflict with the taking of the milk. Antipyretics, like antipyrin, antifebrin, acetanilid, phenacetin, and even quinin (for its antipyretic effects), are absolutely forbidden. Stimulation I reserve for necessity, as indicated by marked nervousness, a rapid and feeble pulse, and for the stage of convalescence. In both instances whiskey is preferred, care being taken to secure a good quality. Of heart-tonics strophanthus is given rather a preference, and I at times resort to hypodermatic injections of strychnin. I have never used the cold baths of Brand; at the utmost, sponging with tepid water seems to be sufficient, though not often employed.

I believe that great care must be taken in feeding a patient in the stage of convalescence. I think it is well to keep him on the milk-diet indicated, increasing, however, the amount if needed, for a week, after the temperature has come to the normal. I then begin to feed very gradually, preferring animal to starchy diet.

It will be seen that the methods employed are quite different from those advocated by others. The strict adherence to a milk-diet is, of course, nothing new, and as far back as 1866 we find Dr. Cotting, of Roxbury, Massachusetts, reporting in the London *Lancet* three hundred and seven cases of typhoid fever treated without drugs of any kind and a mortality of only 10 per cent.

Prof. Osler in his recent publication says: "Milk is the staple article of diet, of which from three to four pints are given in the twenty-four hours." This is about the amount I have used. Dr. Hutchinson says: "Milk as an article of diet is unquestionably to be preferred to all others in typhoid fever."

The administration of turpentine was advocated by the late Prof. George B. Wood and indorsed by Dr. Hutchinson, though the dose employed was greatly in excess of that found in the turpentine-mixture.

For the treatment as a whole, though not in every detail, I am indebted to my colleague, Dr. Edmund J. A. Rogers, of Denver, who, in common with a few of the practitioners there, has used it with great success for a number of years.

In conclusion, my apology for the presentation of an article of this class must be found in the wording of Article I of the Constitution of this Association, which reads: "This Association has for its object the advance of scientific and practical medicine," and it is for the purpose of recording the results of practical observation rather than of scientific investigation that I have dared to detain you thus long.

Dr. Lewellys F. Barker, who has been Fellow in Anatomy at Johns Hopkins University, has been advanced to the position of Associate in Anatomy. He remains also Assistant Resident Pathologist to the Johns Hopkins Hospital.

THE MANAGEMENT OF FACE-PRESENTATION.[1]

BY EDWARD P. DAVIS, A.M., M.D.,
OF PHILADELPHIA;
PROFESSOR OF OBSTETRICS AND DISEASES OF INFANCY IN THE PHILADELPHIA POLYCLINIC; CLINICAL PROFESSOR OF OBSTETRICS IN JEFFERSON MEDICAL COLLEGE; CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE WOMAN'S MEDICAL COLLEGE, ETC.

THE frequency of face-presentation in gestation is variously estimated at 1 in 130 confinements, by German observers; 1 in 276, by French; and 1 in 292, by British obstetricians. A hint, I think, may be taken from these statistics as to the methods of obstetric diagnosis employed in the leading maternities of the world. It is quite possible that the greater frequency with which this abnormality is said to occur among German patients is not to be construed into a belief that German women have more face-presentations in labor than do British women, but that owing to the practice of palpation and auscultation before labor, German obstetricians more often diagnosticate the abnormality than do English and French physicians. The importance of early diagnosis of this complication is indicated by the success of spontaneous labor in these cases, and the mortality that attends labor requiring instrumental aid.

In a recent interesting paper by von Weiss,[2] forty-six cases are narrated of spontaneous delivery attended by no mortality. Zeller, in forty cases terminating spontaneously, lost no mothers and but two children. While these statements are not exhaustive as to the advantage of spontaneous delivery, the fact remains that such a termination of labor in face-presentation is most desirable. Methods best adapted to secure this result must be based upon early diagnosis, and hence the importance of perfecting the knowledge and practice of palpation.

The treatment best adapted to secure spontaneous labor in face-presentations consists in retaining the membranes unbroken until the time of spontaneous rupture; of sustaining the patient's strength and conserving her energies by suitable feeding, stimulation, and anodynes; and in placing the patient in such a posture as to favor the rotation of the chin anteriorly. When the face looks toward the left side of the mother's pelvis, she should lie upon the left side, her thighs flexed, and the uterus brought as nearly as possible with its long axis corresponding to the axis of her body during labor-pains. Should the fetal face look toward the right side of her pelvis she should lie upon her right side. The relation of cause and effect that has been found to exist between obliquity of the uterus in the mother's abdomen, and face-presentation, renders the maintenance of the uterus in a favorable posture during this complication a matter of considerable moment. It is quite possible in such cases for a face-presentation to be spontaneously changed into an occipital one, and for the occiput even to rotate spontaneously to the front, if these precautions are observed. The administration of such substances as tend to maintain efficient uterine contractions is certainly indicated in these cases before the membranes rupture. As soon as dilatation is complete, the obstetrician is to choose between radical interference by version, or an effort by the methods of Baudelocque and Schatz to correct the face-presentation by converting it into an occipital one. His choice in this decision should depend upon the size and shape of the mother's pelvis, the comparative size of the fetal head, and the condition of the pelvic floor. When no disproportion exists between the head and the pelvis, and when the pelvic floor, although elastic and resistant, offers no undue obstacle to the mechanism of labor, it is certainly proper to allow the head, under good labor-pains and with good extension, to come down upon the pelvic floor in face-presentation, and thus an opportunity be given for the mechanism of labor to proceed spontaneously. When, however, there is a disproportion between the head and the pelvis, as evidenced by pelvic proportions less than the average, ascertained by pelvimetry, or a large fetal head, as ascertained by palpation and a thorough vaginal examination under an anesthetic, the case becomes quite different.

The results of forcible delivery in face-presentation under these conditions are anything but satisfactory and encouraging. The literature of the subject abounds in illustrations of difficult deliveries by forceps, craniotomy, and, in some cases, by version, in which the life of the child has been lost and the mother seriously injured. In the light of our present knowledge the duty of the obstetrician lies in completely changing the presentation, if the pelvis be roomy, by podalic version under anesthesia by chloroform, or in so enlarging the pelvis that the mechanism of labor in face-presentation can continue.

Podalic version for face-presentation is familiar as an expedient, and is, in well-selected cases, a prompt and efficient method of treatment. Symphysiotomy is a procedure of too recent date to occupy an established place in these cases in the resources of obstetric art.[1] My reasons for considering this a rational procedure are are as follows: Personal observation in four symphysiotomies done for disproportion between the head and the pelvis has led me to remark the decided increase of the oblique diameters

[1] Read before the American Gynecological Society, Washington, May, 1894.

[2] Archiv f. Gynäkologie, 1893. No. 25.

[1] Under date of June 13th, Dr. R. P. Harris writes me, that he knows of no case of face-presentation in which symphysiotomy was performed to rectify the position.

of the pelvis that follows the separation of the pubic joint. In three of the four cases, the fetal head presented in an occipito-posterior position; in two cases the right occipito-posterior, in one the left. In one of these cases the head presented by the right parietal bone before the pelvis was opened. Remembering the observation by many obstetricians that face-presentations are often developed out of occipito-posterior positions, it seems to me rational that any surgical procedure which should enlarge the oblique diameters of the pelvis, and which naturally favors the descent of the occiput in the arc of the pelvic curve lying between the sacro-iliac joint and the spine of the pubes, would afford rectification of this abnormal presentation. The three cases of occipito-posterior position following symphysiotomy were readily delivered without injury to mother or child.

Obstetricians are familiar with the facility with which faulty presentations of the head and shoulders may be remedied when two conditions are present: first, complete anesthesia of the mother; and second, a pelvis of good size in its oblique diameters. Reasoning from my experience in the cases cited, these conditions are present after symphysiotomy; and were the spontaneous progress of labor in this presentation to fail, I should much prefer, if the pelvis were of good size and the head not impacted, to perform podalic version; or, if the head were impacted, and disproportion existed between the head and the pelvis sufficient to occasion difficulty in labor, the face-presentation persisting, I should hope for a favorable result from symphysiotomy, converting the face-presentation into a vertex-presentation, and delivering the occiput in the manner most easily available after the pubic joint had been opened.

MEDICAL PROGRESS.

Hydatid Cyst in the Neck of a Child.—SMITH (*New Zealand Medical Journal*, vol. vii, No. 2, p. 88) has reported the case of a girl, four and one-half years old, who presented a tense, elastic swelling, as large as an orange, obviously containing fluid, situated beneath the angle of the jaw on the right side, and completely filling the middle triangle of the neck. The skin over the tumor was smooth and non-adherent, and presented no indication of inflammation. The formation was believed to be a "cold" glandular abscess, but an exploratory incision proved the diagnosis to be incorrect. Accordingly an incision was made and the tumor was found to be encapsulated and to contain fluid. Spread out over its deep attachment were the thinned and barely recognizable fibers of the posterior division of the sterno-mastoid muscle. Posteriorly, the tumor was intimately adherent to the sheath of the common carotid artery, displacing to one side the omo-hyoid muscle. Above, it penetrated behind the angle of the jaw and beneath a portion of the parotid gland. In front, it was adherent to the fibers of the sterno-hyoid and sterno-thyroid muscles. Several nerves, including the descendens noni and the hypoglossal, were dissected from the posterior surface of the cyst and all veins were divided between two pairs of pressure-forceps. The only vessel requiring ligation was a branch of the superior thyroid artery. The intimate relations of the tumor rendered its dissection difficult and laborious. On incising the cyst-wall, which was very thick and quite characteristic, it was found to contain clear fluid and a number of smaller cysts, microscopic examination of the contents of which disclosed the presence of hooklets. The patient made an uninterrupted recovery and was dismissed in a fortnight.

Paralysis Agitans without Tremor.—At a recent meeting of the New York Neurological Society, Dr. Frederick Peterson presented a wheelwright, sixty years old, who displayed characteristic mask-like rigidity of the face, with the attitude of paralysis agitans, the stooping shoulders, bent back, crooked elbows and knees. The hand and fingers were held in the characteristic position, but there was no tremor anywhere in extremities or head. The voice had the monotony and something of the festination of the speech of paralysis agitans. There was at times a sort of propulsion in walking.

THERAPEUTIC NOTES.

The Mechanical Treatment of Constipation.—As the result of an elaborate study, based upon a large experience, MARINEL (*Journal de Médecine de Chirurgie et de Pharmacologie*, 1894, tome iii, fasc. 1, 2, p. 1) concludes that the mechanical treatment of constipation constitutes a therapeutic measure acting with great energy upon the circulation, the respiration, and the general nutrition. It brings about a modification of the abdominal circulation, and causes the disappearance of certain conditions of passive congestion, notably those encountered in cases of abdominal plethora. Under its action both the volume and the force of the muscles is increased. It is the best curative agent in the treatment of constipation dependent upon paresis or paralysis of the muscular system of central nervous origin, and also when the constipation is dependent upon hypesthesia or anesthesia of the intestinal mucous membrane of local origin. It is contra-indicated when constipation is due to acute inflammatory lesions or to new-growths.

For Whooping-Cough.—

R.—Sulphonal . . . . . gr. j.
Creasoti . . . . . ♏ij.
Syrup. tolu. } . . . . . āā f ℥ij.
Aquæ }

S.—Two teaspoonfuls every two hours.

Practitioner.

For Lead-poisoning PEROU (*Lancet*, No. 3690, p. 1277) recommends sodium monosulphite in doses of six grains daily. By this means speedy relief from colic is obtained, and the elimination of the lead is also hastened. The agent is besides an efficient prophylactic and its use is unattended with danger.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. HYPNOTISM AND CRIME.

IT has long been apparent that hypnotism was to have sooner or later its medico-legal aspects. When EYRAUD, the strangler of Paris, committed his foul crime he used as a sexual decoy a young woman named BOMPARD. The victim was taken by EYRAUD *en flagrante delicto* with BOMPARD, and so between the two he was neatly strangled. At the trial the astonishing claim was made that BOMPARD had been hypnotized by EYRAUD, to be his accomplice, and this claim was pressed in court to such purpose that the prisoner—probably because she was a woman—was merely imprisoned instead of being guillotined. Specialists in hypnotism (for there are such specialists in France) urged that the process in BOMPARD's case had been by *suggestion;* and a critical outside world exclaimed that almost all evil had been by suggestion ever since the first séance between EVE and the serpent.

It is interesting to note now the appearance of an ambitious treatise by CROCQ[1] on *Hypnotism and Crime*, in which this author opposes the theory of an hypnotic influence in the case of BOMPARD, and proceeds to work out in his own way both a theory and its application for this somewhat abstruse subject. After an admirable historic survey, CROCQ defines hypnotism as a "particular state" developed under the influence of the concentration of all the intellectual faculties upon one point. This hypnotic state is inseparable from an initial hypnotic sleep, which may manifest itself as well in healthy as in unhealthy or hysterical subjects. It presents various stages, all allied to a somnambuloid state. In this particular mental state suggestibility is a marked feature, *i. e.*, the subject may be led to commit automatically a variety of acts, including criminal deeds, without always retaining a distinct recollection of them after returning to the norm.

It will be seen at once that this is a more critical and exact statement than that of the school of Nancy, which in BOMPARD's case defined hypnotism to be practically identical with suggestion. It is one thing to say that suggestion is hypnotism, but a vastly different thing to say that hypnotism is a special state in which suggestion may act with increased force. The first proposition is untenable, because practically it reduces all influence of mind upon mind, hence most of education and much of morals, to the level of a psychosis; the second is scientific, because it affirms merely that in a special psychosis, *i. e.*, the hypnotic state, suggestion has a pathologic significance. So far we think the statement of CROCQ is exact and the theory valid. The exceptions that we take to this clever and intellectual French (or, to be accurate, Belgian) treatise have reference to some refinements of definition and to some of the applications of the theory in special cases.

CROCQ is inclined to draw too fine a distinction between "hypnosis" and some of the well recognized psychoses—hysteria, for example. We demur to this, especially when the author claims that hypnotism can exert an influence upon perfectly healthy minds, unless he is willing to include the various grades of hysteria within the limits of perfect health, which is doubtful. We think that the genuine hysterical state is closely analogous to, if not identical with, a condition of hypnosis. We see in hysteria that kind of hypnosis known as double consciousness, with contraction of the field of consciousness and extreme suggestibility. Wherein does this differ from hypnotism? In nothing, except that one is a condition, the other a method; one is inherent, the other induced; one is natural, the other artificial—vain distinctions, from the critical standpoint.

[1] "L'Hypnotisme et le Crime." Par le Dr. Crocq, Fils. Bruxelles: Henri Lamertin, Editeur. 1894

The practical part of CROCQ's book lies in its application. Crimes are considered *seriatim*. Rape, theft, the substitution of infants, false testimony, murder, and suicide are the chief among these. The quality of this part of the book cannot be judged by an isolated quotation, but one case may be cited as illustrating the author's acumen and naïveté. A young woman, who was hysterical and somnambulistic, left PITRE's service at Bordeaux, "absolutely and surely a virgin." She was accompanied by another hysteric. They soon encountered two gentlemen, who took them to breakfast. Hysteric number one was embraced by one of the gentlemen, in spite of the fact that she became violently angry. She defended herself; she even *threatened* to cry out. But it was useless. Her suitor hypnotized her; she lost consciousness, and "*Neuf mois après ce jour la jeune fille accouchait d'un enfant à terme.*" This is a clear and logical conclusion. The simplicity of the tale is exceeded only by the simplicity of the mind that finds in it the evidence of a psychosis.

All of CROCQ's examples are not of the same sort as this, and some have in them more evidence of the mental state that is now such a favorite object of study in Paris. When, however, we think of one of our average American courts or juries devoting itself to a conscientious study of this book we experience a hope that the future translator will edit carefully the illustrative cases. The ordinary American juryman would not put faith in a virgin "absolutely pure," who picked up a strange man on the street and held with him a salacious "hypnotic" séance in a neighboring saloon. The verdict, we fear, would not sound well to ears polite.

It may be for the modern Athenians to take the lead in this new province of medical jurisprudence; and until we see how they manage these things in France we shall rest content with the admirable light from M. CROCQ's book.

EDITORIAL COMMENTS.

Fever without Pyrexia.—We have on previous occasions called attention to the apparent paradox of the occurrence of febrile conditions without elevation of temperature. In the course of a recent clinical lecture, TEISSIER (*Semaine Médicale*, No. 25; *Wiener med. Presse*, 1894, No. 23, p. 893) presented a case of pneumonia attended with a subnormal temperature, and made some interesting comments. He pointed out that the temperature may pursue a similar course in undoubted cases of scarlatina, as well as in cases of typhoid fever and influenza. He also made reference to two cases of typical malarial fever attended with subnormal temperature. These were not cases of pernicious malaria of algid type, but were intermittents of moderate intensity, and in which quinin brought the temperature to the normal. Several explanations of this anomalous occurrence have been offered. One of these makes it dependent upon the varying reaction of the thermotaxic centers to varying degrees of virulence of the infecting organisms, a slight degree inducing hyperthermia and an intense degree hypothermia. The inadequacy of this explanation is evident from the fact that it is not always the gravest cases that are attended with hypothermia, and *vice versa*. Rather more plausible is the explanation that pathogenic microorganisms give rise to the production of substances that cause elevation and of others that cause depression of temperature. Finally, it is possible that the hypothermia is due to the accumulation in the body, from failure of elimination, of excrementitious products by reason of hereditary tendencies or of renal inadequacy. The action of quinin in causing elevation of abnormally low temperature is to be ascribed to its vaso-constrictor action, thus preventing undue radiation of heat. Among other measures to be adopted is the stimulation of the cutaneous and renal activity. All in all, the subject is a most interesting and suggestive one. It would seem as though we would have to modify, or at least qualify, the current conception and definition of the febrile process. The problem here propounded is but one of many for the solution of which we must look to chemic physiology.

The Judicial Council.—"Our esteemed contemporary, the Philadelphia MEDICAL NEWS, states that the question of the 'conduct of *The Journal*' was referred to the Judicial Council and has not yet been decided by them.

"At the last meeting of the Association, the question of the action of the management of *The Journal* in publishing certain advertisements was considered by the Judicial Council, and after a full hearing in the matter, the Council decided to leave it as heretofore in the hands of the Trustees."—*The Journal of the American Medical Association*, July 7, 1894.

Our cotemporary is characteristically inexact. Its insertion of the words "by them" after the word "decided" alters the meaning of our statement. We said that "the question of the conduct of *The Journal* is not yet decided"; and that "for the present discussion may well be suspended." We repeat the statement.

We also said that we were not yet informed as to the action taken by the Judicial Council on the points submitted to the Council by the MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA, and by the resolution of DR. EDWARD JACKSON referred at San Francisco. Our cotemporary but partially enlightens us. Until the full text of the decision is published, we cannot assume that our cotemporary correctly interprets it, seeing that our cotemporary sometimes makes errors of interpretation in other matters; nor can we comment upon the decision whether or not our cotemporary is correct in its interpretation thereof, until the reasons therefor are before us. We await the full text with much interest and trust it will be promptly made public.

Protective Inoculations against Cholera.—The success of the method of inoculation devised and practised by M.

Haffkine as a means of protection against cholera is being put to a practical test in India. Within a year or thereabouts some 25,000 persons have been already thus inoculated, but hitherto the crucial experiment of exposure to an epidemic of the disease had not been made. It is now authoritatively reported that in a community of two hundred inhabitants near Calcutta, in which cholera broke out, and of whom one hundred and sixteen submitted to the inoculations, ten persons, none of whom had been inoculated, were attacked and seven died. Of a family consisting of eighteen persons in which a fatal case of cholera occurred, eleven submitted to inoculation. When cholera again broke out in the same house at a later date, four persons were attacked, none of whom had been inoculated, and three died. In another instance four of six members of a family were inoculated several months ago; recently when cholera appeared one of the two uninoculated was attacked, while all of the inoculated escaped. In a family of eleven, five were vaccinated; one of the six not inoculated was attacked. Six of a family of nine were inoculated; one of the three not inoculated was attacked. In all instances those inoculated escaped. The number of cases thus far treated it will be admitted is too small to formulate final conclusions upon, but the results are, to say the least, encouraging and the hope will be universal that they may be abundantly confirmed by more extended observations.

Milk-inspection.—The practical advantages of an intelligent and systematic inspection of milk for domestic use are admirably illustrated by the report of the Inspector of Milk of the city of Boston, who announces a distinct improvement in the quality of the milk served to families as a result of the vigilant enforcement of the inspection-laws. The fines imposed for failure to conform to the standard established were more than sufficient to pay the expense of the inspections. Two things, however, are absolutely essential for successful results in this connection: (1) the enactment of practical and intelligent legislation, and (2) its faithful and rigorous execution.

REVIEWS.

The Healing of Rodent Cancer by Electricity. By J. Inglis Parsons, M.D., M.R.C.S., M.R.C.P. (Lond.), etc. Small 8vo, pp. 82. London: John Bale & Sons, 1893.

The title of this little book would be more correct if the word "destruction" were substituted for "healing." For the author distinctly says (p. 10): "My aim has been to adjust the strength of the electric current so as to kill the malignant cells, yet not to injure the healthy cells beyond recovery." When the morbid structures have been completely extirpated, whether by the knife, by caustics, or by electricity, healing may be expected to take place as in an ordinary simple ulcer.

After a discussion of the pathology and clinical characters of the disease (based, we judge, upon a communication by Mr. Jackson Clarke, on "Parasitic Micro-organisms in Cancer," in vol xliv of the *Transactions of the Pathological Society of London*), a very good "outline of elementary principles for the benefit of those who have not studied electricity" is given. The advantages of this agent are next expounded, and then the author's method of using it is explained. Finally, the details of four cases are presented. So far as appears, these comprise the whole of the author's experience in this direction.

Very possibly a surgeon unfamiliar with the employment of electricity, if called upon to treat a patient with rodent carcinoma, might find some assistance in these pages.

The Technique of Post-mortem Examination. By Ludvig Hektoen, M.D., Pathologist to the Cook County Hospital, Chicago; Professor of Pathologic Anatomy in the College of Physicians and Surgeons of Chicago. With 41 illustrations. 8vo, pp. viii, 172. Chicago: W. T. Keener & Co., 1894.

In this little book Dr. Hektoen reflects the good pathologic work that he is doing in Chicago. Perhaps the greatest defect of the American medical curriculum has been in the department of practical pathology, and it is gratifying to notice a growing tendency to improvement in this direction. The fault lies in some degree in custom and education, for post-mortem examinations are far less common in the United States than they should be. The work of the Coroner's office in most cities is not calculated to invite the admiration of the earnest pathologist, either in its execution or in its results, and we take this occasion to express the hope that the future has better things in store for scientific medicine. Dr. Hektoen has provided us with an excellent guide in post-mortem examinations, which we can heartily commend to both students and medical men. Every student should be familiar with this technique, not only from reading, but also from observation and practical experience.

The Microscope and Microscopical Methods. By Simon Henry Gage, Associate Professor of Anatomy, Histology, and Embryology in Cornell University. Fifth edition; rewritten, greatly enlarged, and illustrated by 103 figures in the text. Part I. The Microscope and Histology. Pp. 165. Ithaca, N. Y.: Comstock Publishing Co., 1894.

This new edition of a most useful book has been enlarged by the addition of a new chapter on photo-micrography and allied matters. The number of illustrations has also been considerably increased. Their distribution in the text is an advantage over grouping a number together. We need not repeat the words of commendation it gave us pleasure to express in reviewing the third edition (The News, April 30, 1892, p. 502). The book remains a most practical and intelligent guide for the beginner, who so often finds difficulty in becoming well grounded. The work bears the impress of the laboratory, and it is largely on this account that it commends itself. We await with much interest the appearance of the second part of the work, which, it is announced, is in preparation and may be expected in the course of two years.

Prof. Madelung has been appointed Professor of Surgery in the University of Strassburg, in succession to the late Prof. Lücke.

SOCIETY PROCEEDINGS.

AMERICAN PEDIATRIC SOCIETY.

Sixth Annual Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

First Day—May 29th.

The meeting was called to order by the First Vice-President, Dr. Forchheimer, of Cincinnati.

Dr. B. K. Rachford, of Newport, Kentucky, read a paper entitled "The Influence of Venous Congestion on the Spinal Reflex Centers." He maintained that three important changes in the blood bear an etiologic relation to the neuroses of childhood, viz.: (1) the presence of toxins; (2) simple anemia, acute or chronic; (3) venous congestion, acute or chronic. These do not exist as separate etiologic conditions, but as factors of the complex blood-condition that has much to do in producing the excitability associated with the chronic anemias of childhood. He called attention to the fact that toxic products may produce nervous symptoms, and may therefore be etiologically important in the neuroses of childhood. There are other toxins in the body besides those of bacterial origin. Paraxanthin is a poisonous leukomaïn of the uric-acid group, and is an etiologic factor in a group of nervous symptoms that has heretofore been ascribed to uric acid. Dr. Rachford starved and bled a number of rabbits into a condition of profound malnutrition, and was led to suspect that the blood-changes in scrofula, malaria, rheumatism, and other blood-diseases might not be simply the result of anemia, but that the blood might also contain effete and poisonous products that might also help to keep the nervous system in a state of chronic irritability. This view had been confirmed by ligation of the abdominal vena cava in the rabbit. This experiment had shown that a most exaggerated reflex irritability of the spinal cord might be thus produced, but that the reflex irritability did not begin until the end of the second week after the operation, and that from this time on for a period of six or eight weeks, it continued to increase. Too much stress is not to be laid on this as indicating excitability of the spinal cord, as it might have been due to the changed condition of the muscles, and nerves, and cells, and not to the state of the cord. The same results were obtained in the rabbit by ligature of the abdominal aorta. The reflex phenomena produced by starvation were very insignificant when compared with those produced by venous congestion or arterial anemia. It seems fair to conclude, therefore, that venous congestion and arterial anemia do not act solely by malnutrition, but that there are additional factors, and that these are to be found in the effete and poisonous products of metabolism kept in contact with the nervous system instead of being eliminated. It seems probable that a similar explanation might be applied to the development of chorea and other nervous affections in children in the sequence of endocarditis and pericarditis.

Dr. T. M. Rotch, of Boston, said that from a clinical standpoint he was thoroughly in harmony with the views expressed. Almost every clinical observer must have noticed the relation between a feeble circulation and the existence of nervous disorders.

Dr. Augustus Caillé, of New York City, read a paper on "Tonsillotomy followed by Diphtheria and Croup." He reported the case of a boy, four years old, who had been brought to him for the removal of hypertrophied tonsils. Adenoid vegetations were found on digital examination, and the gums were somewhat swollen from caries of the molar teeth. At the request of the parents, who lived at some distance from New York, Dr. Caillé decided to operate at once, without carrying out his usual prophylactic treatment. Both tonsils were removed with a disinfected tonsillotome. The parents were instructed to use Labarraque's solution. The boy was also given internally potassium chlorate every hour, as he was unable or unwilling to gargle his throat. The next day he was violently sick. The stumps of both tonsils were covered with pseudo-membrane, and there was vomiting and cerebral symptoms. A culture was made from the pseudo-membrane and from the carious teeth, and this showed Loeffler bacilli and streptococci—a mixed infection. The boy was given a spray of mercuric-chlorid solution, to be applied to the mouth and pharynx every half-hour. He was also given internally minute doses of mercuric chlorid. The voice became somewhat husky. On the next morning a small streak of diphtheric deposit had appeared on the posterior pharyngeal wall, and a croupy cough was well marked, while the epiglottis was highly congested. Twelve hours later, the posterior surface of the epiglottis was covered by a thin deposit, and the laryngeal stenosis had increased. Intubation was performed on the following morning. The internal administration of mercuric chlorid was discontinued, but a spray of a saturated solution of boric acid was continued. There was a purulent discharge from the tube, and this was removed. The pseudo-membrane deposited on the tonsillar pharynx remained visible a few days longer. The boy ultimately recovered, and three weeks afterward the adenoid vegetations were removed from the pharynx.

Dr. A. Jacobi, of New York City, said that for twenty years he has been teaching the importance of not operating during the prevalence of diphtheria in a community, and especially in cases in which the tonsils are to be removed. Hundreds of times had he seen the wound of an exsected tonsil covered with a thick pseudo-membrane, and in many instances this had been followed by general diphtheria.

Dr. H. Koplik, of New York City, expressed surprise at the large number of tonsils that harbored the Loeffler bacilli in the very depths of the lacunæ. Children with large tonsils are very prone to attacks of lacunar amygdalitis. Virulent diphtheria-bacilli were found in the depths of the lacunæ—not on the surface. By making a culture from the tonsils previous to doing any operation upon them, one can, after the lapse of forty-eight hours, tell positively whether diphtheria-bacilli are present or absent. Diphtheria does not usually develop when no operation is performed on the tonsils, because as long as the diphtheria-bacilli remain in the lacunæ they are bathed in the lymph which exudes into the lacunæ, so that they are under the influence of leukocytes, and their virulence is diminished. Non-virulent bacilli replace the virulent form after the bacilli have remained in the tonsil several weeks.

Dr. Dillon Brown, of New York City, agreed as to

the importance of using antiseptic lotions both before and after naso-pharyngeal operations; in certain cases, however, it is difficult to carry out this precaution. Under such circumstances the use of antiseptic vapors, such as the fumes of sublimed calomel, is to be advised.

DR. F. HUBER, of New York City, read a paper entitled "Congenital Constipation." He said that beside constipation from other causes, there is a congenital variety dating from the first hours of life, and dependent upon the normal anatomy of the colon. The alvine evacuations are dry and insufficient, the watery elements having been absorbed in the reduplication of the colon. Dr. Huber reported the case of a boy, five weeks old, who from birth had suffered from constipation and cramps. The child was healthy in appearance, but evidently suffering great pain. He was straining, kicking, and crying. He had vomited for two days; the abdomen was swollen and tympanitic, and there was an indistinct, elongated swelling to be felt across the abdomen, two inches above the level of the umbilicus. His temperature was 102° F. By a process of elimination and exclusion, a diagnosis was made of acute intestinal obstruction from birth, with impaction of feces in the reduplication of the sigmoid flexure. In many cases the affection is trivial, but in others it is very serious, and might even jeopardize life. The ascending and transverse colon being very short in the fetus and the newborn, and the descending colon very long in proportion, the latter is crowded down into a narrow pelvis, and thrown into a number of curvatures instead of into one sigmoid flexure. The intestinal contents are therefore retarded, the fluid absorbed, and the feces, becoming hard and dry, give rise to obstruction. The treatment consists in distending the lower bowel with fluid, whereby the reduplications are gradually unfolded from below, and the patency of the gut is restored. High rectal injections should be given, and it might be necessary to continue this treatment for years before the proper relation has been established between the colon and the sigmoid flexure. Crying or any increase in the abdominal pressure should be carefully avoided.

DR. W. L. STOWELL, of New York City, said that by a persistent use of ox-gall and sweet oil, and sometimes turpentine, when hard scybalous masses are present, either in infants or adults, he had always been able to move the bowels in these cases.

DR. FRUITNIGHT said that as many of these cases of constipation are due to an unusual dryness of the feces, the free administration of water should not be neglected, in order to favor the solubility of the alvine contents.

DR. J. C. WILSON, of Philadelphia, read a paper entitled "A Case of Malignant Measles," which is to appear in a future number of THE NEWS.

DR. FORCHHEIMER requested that in the discussion the frequency of second attacks of measles be considered.

DR. ROTCH placed himself on record as believing that measles could occur several times in the same individual.

DR. FRUITNIGHT said that he had seen measles three times in the same person, occurring between the second and fourteenth years.

DR. STOWELL said that in a large dispensary practice he had seen a great many cases of measles duplicated.

DR. FORCHHEIMER stated that he had found the occurrence of second attacks of measles in the same person very common, and it was not uncommon to have a third attack, not to say anything about German measles occurring in the intervals between these attacks.

DR. SEIBERT said that in a very extensive dispensary practice he had never had the opportunity of making the diagnosis twice in the same child. While believing, therefore, that it was possible for the disease to occur twice in the same individual, he thought it was not nearly of so frequent occurrence as some would have us believe.

DR. WILSON, in closing the discussion, said that he had had associated with him in consultaton in the case he had reported, Drs. Pepper and Da Costa, and they had all agreed as to the diagnosis.

SECOND DAY—MAY 30TH.

As part of the discussion on "The Etiology, Prevention, and Treatment of Rickets," DR. IRVING M. SNOW, of Buffalo, read a paper entitled "The Influence of Race, Especially the Italian Race." He said that in the community in which he practised, rickets was six times more prevalent among Italians than among the other classes, and that the disease prevailed but to a moderate extent among the children of the English, Germans, Irish, and Poles. He thought that the reason for this was to be found in the change of environment, which was so great for the Italian, who in his native land had lived in a mild, clear climate, with plenty of sunshine, and out of doors for most of the year—a climate very different from that of Buffalo. The change had been too sudden and too severe. The mean winter temperature of Buffalo is 27.15°, and that of Naples 48°. In spring, the mean temperature of Buffalo is 43°, that of Naples 58°. It is certain that rickets is seldom developed among the natives of Southern Italy, Egypt, and India, and this fact is probably accounted for by the out-of-door life of the people and the bright warm sunshine of the climate.

DR. GEORGE N. ACKER, of Washington, D. C., read a paper on "The Influence of the Negro Race." He referred to the many peculiarities of the negro race and the differences between it and the white race. He said that since the war the conditions affecting the negro had been entirely changed. The slaves had food conducive to health and were warmly clad; they lived in healthful houses and were cared for when sick. Now the negroes have to work for themselves; they are shiftless and intemperate; they breathe impure air; wear insufficient clothing, and live in total disregard of all sanitary rules. All this has necessarily exerted a deleterious effect upon their offspring. The race is undergoing serious decay. The diagnosis of rickets can easily be made in the negro if search be made for the usual evidences of the disease. The bone-lesions often appear late and are not always found, so that some severe cases are overlooked. A most important etiologic factor is heredity. The parents are as a rule tuberculous or syphilitic. In Dr. Acker's experience it is common for children with the tuberculous or syphilitic diathesis to develop severe rickets. On account of their unsanitary surroundings and the lack of care given them, the health of their offspring was liable to become considerably impaired. If breast-fed, they failed to receive nourishment at regular hours, as most of the mothers were in service, and other and improper food was given. The negro infant is weaned at an early age; it is not uncommon to find

infants of a few months old fed on condensed milk, oatmeal, beef-tea, bread and butter, and tea. Between the sixth and eighteenth months of life pulmonary disorders are very common, and it is at this time of life that rickets is most frequently observed. Disease of the respiratory organs lowers the vitality, and in this way might be considered an etiologic factor in causing rickets. The pathologic changes found in rickets are about the same in negroes as in other races. Enlargement of the wrist-joint is more prominent; the swelling of the ribs occurs earlier and is more constant; the thoracic grooving is marked in all cases. The head is rectangular, but this is not a constant feature. In some cases the fontanels close early and the skull is firmly ossified. Although Dr. Acker had made careful search for cranio-tabes, his experience has led him to think it quite rare among the negroes. As negroes have less susceptible nervous systems than whites, they are less liable to nervous diseases. When these rickety children are placed in more favorable surroundings the disease usually yields quite readily to treatment.

DR. C. W. TOWNSEND, of Boston, reported "A Case of Congenital Rickets." The child was seen at the Boston Lying-in Hospital, and was born of healthy parents who had no syphilitic history. A previous child had been born to these people and up to the age of three years had shown no signs of rickets. The parents were wretchedly poor; the child was a male, premature, and weighed seven pounds. His head was sixteen inches in circumference; the sutures were widely open; there was a large area of cranio-tabes; Wormian bones were present; there was considerable cyanosis, which might have been partially due to an open ductus arteriosus. No murmur was heard over the heart. There was the characteristic rickety rosary; the abdomen was large; the spleen could not be felt; the extremities showed evidences of rickets, enlargement of the epiphyses being easily noticeable. The bones of the forearm were bent posteriorly; the femur was curved outward and forward. These curvatures could only be explained by the action of the muscles on the soft bone *in utero*. There were also fractures due to the extreme brittleness of the bones, a late phase in the rickety process, and therefore they must have been produced by muscular action within the uterus. The child was artificially fed, and died on the ninth day. There was no autopsy.

DR. J. P. CROZER GRIFFITH, of Philadelphia, remarked that he had not been able to observe any difference in the causation of rickets in the colored and in the white race. It seemed to him reasonable to suppose that at least the colored children of Philadelphia should have become acclimated by this time.

DR. L. EMMETT HOLT, of New York, said that the most severe cases of rickets seen in New York are among the negroes and Italians. The causes of rickets are many and far-reaching. The predisposition of these two races seemed to be unquestioned, and he has been led to about the same conclusions as those reached by Dr. Snow.

DR. J. HENRY FRUITNIGHT, of New York City, said that it would seem that the nations of Continental Europe are more liable to rickets than are the inhabitants of the British Islands. He also mentioned a case of congenital rickets which he had seen, thus making four cases on record in this country.

DR. A. SEIBERT, of New York City, called attention to the fact that in by far the majority of cases of rickets he had found cranio-tabes since he had made it a practice to especially look for this condition. He said that it should be especially looked for if there is any history of eclampsia.

DR. JOSEPH E. WINTERS, of New York City, said that climate has an influence in producing rickets, but that it is not climate alone, but the way in which it influenced assimilation and digestion. Every one of these cases, notwithstanding the change of climate, could be cured with proper food. With reference to tuberculosis and rickets, Dr. Acker had stated that tuberculosis and rickets were associated conditions. Dr. Winters said he had yet to see a tuberculous child become rickety. He thought that if a child suffering from tuberculosis were subjected to the conditions that induce rickets, the child would die before rickets had developed.

DR. H. KOPLIK, of New York City, said with reference to the value of drugs in the treatment of rickets, that he favored the administration of phosphorus in the daily dose of $\frac{1}{120}$ of a grain, and he thought this treatment led to very satisfactory results if persistently kept up.

DR. ACKER, in closing the discussion, expressed his opinion that if placed under proper surroundings the negro would be cured of rickets without resort to any drugs.

DR. A. SEIBERT, of New York City, read a paper entitled "An Aid to the Sterilization of Milk in Artificial Infant-feeding." He called attention to a method of cleaning milk before sterilization, thus enabling everyone to remove the gross filth from the milk, and at the same time diminish the number of bacteria contained therein to a remarkable degree. He had made a number of experiments that showed that seven-eighths of the bacteria were removed from a given bulk of milk by filtering through absorbent cotton. He had also experimented to ascertain whether the amount of cream or the specific gravity of the milk was changed, and he had found that the milk was not altered by the filtration through a one-half-inch layer of compressed absorbent cotton, and also that the quantity of sugar was not diminished. At his request, Dr. Otto Kiliani, of New York City, had made some control bacteriologic experiments. These experiments showed beyond a doubt that filtering the milk reduced its germinating capacity considerably, and that the purifying quality of the cotton was decidedly intensified by moistening it before filtration. By this process Dr. Kiliani had been able to reduce the bacteria to one-twentieth of their original number. A quart of milk could be filtered in from twelve to fifteen minutes. All the apparatus necessary is an ordinary funnel in the bottom of which the absorbent cotton is packed.

DR. KILIANI said that his share of the work had only consisted in performing the control-experiments alluded to. As a proof of the care with which these were conducted, he mentioned the fact that out of nineteen experiments not a single culture had been obtained as a result of infection from the hands or from the air.

DR. SEIBERT said that in presenting this method for purifying milk he did not wish to be understood as opposing sterilization in the ordinary manner. On the contrary, he would now sterilize more than ever, because

he knew that he could give his patients more completely sterilized milk than he had hitherto been able to do.

Dr. J. Henry Fruitnight, of New York City, read a paper entitled "Infantile Scurvy, Especially its Differential Diagnosis." He said that since the writings of Barlow and Northrup, and others, infantile scurvy had been much more frequently diagnosticated than before. As scurvy is a disease resulting from faulty nutrition, it could be safely assumed that more cases are encountered now than when breast-feeding was more general. He described in detail a typical case of infantile scurvy. When this child first came under observation it was in a deplorable condition. There was a fusiform swelling of the left ankle and a swelling of the thigh on the same side, both of which were very painful; the temperature was 100°; the pulse feeble and very rapid; the gums dusky-purple; the tongue and cheeks were ulcerated, and the whole mouth was inflamed and emitted a fetid odor. The slightest touch induced bleeding from the gums. There were petechial spots over the back and limbs. The right eye was closed by ecchymosis; the conjunctiva was involved in this effusion, and the swelling extended far down on the cheek. There was considerable blood in the stools, but the child did not have diarrhea. It was extremely anemic. Although it was evident that the prognosis was not very encouraging, treatment was instituted, and the child recovered completely at the end of six or seven weeks. The chief point in treatment was the change of food, Pasteurized milk being ordered, together with orange-juice and citrate of iron. In recovering, the patient first improved in the leg, then in the mouth and gums, and the hemorrhagic spots were the last to disappear. Dr. Fruitnight believed that the condition of malnutrition present in scorbutus could not but exert a special influence on the bloodvessels. The most important cases of scurvy had not been rickety, although the disease had been formerly diagnosticated as acute rickets. It was an error to suppose that scurvy never occurred in breast-fed children. The chief points on which the diagnosis was made were the swelling and tenderness of the ends of the femur, the swollen and spongy condition of the gums, and the rapid and complete cure that followed a resort to antiscorbutic treatment. The condition might be mistaken for acute rheumatism. In scurvy the joints are white and tense, but not puffy; in rheumatism the joints are red and puffy, and the tenderness is localized in certain spots. In scurvy there is no local elevation of temperature; in rheumatism there is such an increase in the local temperature. The diagnosis is, of course, more difficult when only poorly-marked joint-symptoms are present, and here the therapeutic test should be resorted to to decide the question of diagnosis. It had been said that this would expose the patients to endocarditis by delaying the treatment if the case were one of rheumatism; but if the symptoms do not quickly abate there is sufficient reason for believing the case to be one of rheumatism, and the appropriate treatment for this disease could then be immediately adopted. The pseudo-paralyses found in infantile scurvy require to be differentiated from other infantile paralyses. They could only occur from bone-lesions in scurvy, and these should be looked for. Scurvy might be looked upon as the result of a faulty nutrition leading to the deviation of the normal constitution of the blood, probably as a result of deficient alkalinity. It is also associated with changes in the bloodvessels. The three important symptoms are the bone-lesions, the spongy condition of the gums, and the petechiæ. The symptoms appear first in the lower extremities, then in the gums, and lastly the hemorrhagic extravasations appear. The disease usually runs a favorable course under a proper dietetic treatment.

Third Day—May 31st.

Dr. W. S. Christopher, of Chicago, read a paper entitled "The Nutritional Element in the Causation of Neuroses." He said that the following positive factors are present in all neuroses: (1) heredity; (2) anemia; (3) some local condition acting reflexly as the immediate exciting cause. Clinically, the nutritive quality of the blood can only be determined by an estimation of the quantity of hemoglobin and the number of blood-corpuscles present in a given quantity of blood. Such an examination, however, does not furnish very satisfactory evidence. A neurosis was described as a group of phenomena resulting from such abnormal action of tissue or tissues as might be dependent upon one or more of the following conditions: (1) abnormal chemic constitution of the tissues; (2) abnormal chemic composition of the nutritive elements supplying the tissues; and (3) derangement of the nerves. Each individual requires not only a certain quantity of food but also a certain variety, in order to meet the various chemic requirements of the human organism. The proteids, carbohydrates, and fats do not supply the needs entirely. Aside from salts and water, there are other things that probably act as food. The nutritional antiscorbutic element has as yet escaped detection by the chemist. It is needed in comparatively small quantities, and it might be withheld without detriment for a considerable time. If food were sufficient in kind but deficient in quantity, the result would be complete starvation. When the food is deficient in variety, the result would be incomplete or partial starvation. This partial starvation is an important factor in the production of neuroses. It is most commonly present in infants in the form of fat starvation, which was natural enough when one remembered the very large consumption of commercial infant-foods at the present time. Proteid starvation is much less frequent. In the causation of changes in the tissues there were other factors besides interference with the food-supply, *e. g.*, abnormal nerve-impulses, direct toxic action, and pathologic conditions affecting the organism, such as syphilis and infectious diseases. In conclusion, it was stated that neuroses are always dependent upon abnormal chemic constitution of the tissues, and that such a condition might result from one of three factors, viz: (1) heredity; (2) deficient constructive metabolism, which might follow from insufficient food-supply; (3) deficient destructive metabolism.

Dr. Rotch, of Boston, stated that infants vary greatly in their individual requirements in regard to the quantity of fat needed by the organism.

Dr. William P. Northrup, of New York City, reported "A Case of Cyanosis," and demonstrated the lesions found in the heart. The patient was a boy, four-and-a-half years old, who, although apparently well nourished,

had pale cheeks and dusky lips and fingers. The digits were knobbed and the belly prominent. Three or four times each week he suffered from very severe attacks of dyspnea, and he also had more or less dyspnea after meals. Palpation showed a fine wave at the left third interspace; there was a soft purring thrill over the base of the heart; the apex-beat was half an inch outside of the left nipple-line; cardiac dulness extended from the right sternal border to the left nipple; there was no dulness to the right of the sternum. A loud, harsh, systolic murmur was heard along the left margin of the sternum, and was distinctly localized at the second left interspace at its junction with the third rib. This murmur was not transmitted to the left or along the aorta. The second sound of the heart was scarcely audible. At the autopsy the right ventricle was found to be markedly hypertrophied, tilting the heart to the left. The apex of the heart was to the outside of the nipple-line, and no part of this organ extended to the right of the sternum. The aorta was distended; the pulmonary artery was unusually small; the ductus arteriosus was impervious; the foramen ovale was practically closed; the left ventricle was normal; the walls of the right ventricle were thicker than those of the left; the septum was incomplete at the auricular extremity; the conus arteriosus was constricted. A probe could not be easily passed from the pulmonary artery into the right ventricle because the pulmonary orifice was at right angles to the axis of the artery, and was very small. The case was one of early fetal endocarditis, giving rise to constriction of the conus arteriosus. This endocarditis must have occurred early in development, before the septum was completed, so that Nature could elect the very best point to effect a compensatory circulation. The aorta, receiving a direct stream of blood from both ventricles, was distended; the pulmonary artery, receiving very little blood, remained small.

Dr. T. M. Roch, the Chairman of the Committee on the Nomenclature of Diseases of the Mouth, then presented the report of the committee. He said that there should be uniformity in the designation of diseases, so that a disease would be called by the same name wherever it was written or spoken about, and that the nomenclature offered by the committee was intended to aid in the accomplishing of this object. The term stomatitis was taken as a basis, and from this four divisions were made: (1) stomatitis catarrhalis; (2) stomatitis herpetica or aphthosa; (3) stomatitis ulcerosa; and (4) stomatitis mycetogenetica. These were again subdivided; for example, stomatitis catarrhalis was subdivided into (1) stomatitis secondary to the exanthemata; and (2) traumatic stomatitis. The report of the committee was accepted by the Society.

The Committee on the Nomenclature of the Diseases of the Gastro-Enteric Tract then presented its report. This consisted of a schematic classification of these diseases. There were two grand divisions—gastric and enteric—and the chief subdivisions were (1) developmental; (2) functional; (3) organic. There were also many subdivisions of each one of these grand divisions. The report was accepted after some discussion.

Dr. Dillon Brown, of New York City, then read a paper entitled "The Early Diagnosis of Pott's Disease of the Spine in Children." He divided the symptoms into three groups: (1) Those common to all cases of tuberculosis, such as peculiar night-cries and evening rise of temperature; (2) the peculiar attitude and rigidity of the spine; (3) the symptoms secondary to interference with the spinal cord and nerves, such as paralysis and dyspnea. In all cases of curvature of the spine the deformity is rounded and not angular. Psoas contraction is almost pathognomonic of spinal caries.

Fourth Day—June 1st.

Dr. William P. Northrup, of New York City, read a preliminary paper on "Infantile Myxedema," as illustrated by two cases which he reported. The first case occurred in a female child, nine years old, four healthy children having been born previously. The parents were Irish and American, and were strong and healthy. The subject of this report had practically ceased developing at the age of nine months, and when seen, at the age of nine years, was mentally no older than when nine months old. The head was large; the color peculiar, yellowish, and tallow-like; the hair thin; the bridge of the nose characteristically flattened and the nostrils tilted back; the lower lids diffusely swollen; the cheeks pendulous; the lips thick and anemic; the tongue swollen and protruding; the gums filthy and suppurating; the breath emitting a peculiarly characteristic and offensive odor; the soles of the feet dry and parchment-like. The thyroid gland did not seem to be especially enlarged. The only words the child would say were "Dada;" and it would sit for hours at a time tied in a chair. There were some evidences of rickets. For four days after the child was admitted to the hospital no treatment was instituted, in order that the natural course of the temperature might be observed. It was found that the rectal temperature varied between 97.5° and 99.5°. A reliable glycerin extract of the sheep's thyroid was then administered, the doses being so regulated as to keep the rectal temperature just below 100°. Four minims of the extract formed the highest daily dose given. On the fourth day the temperature overstepped the limit, and the thyroid extract was stopped for a short time. Two days later, the breath had become less offensive. While under observation the child had an attack of acute pneumonia, and this necessitated stopping the treatment for a while. The tongue swelled while the thyroid extract was suspended, and again diminished in size on resumption of the treatment. After eighty days of treatment, it was found that the tongue was smaller; the countenance brighter; that the child was better in appearance and more good-natured, and that there was no excessive perspiration. There had, however, been no increase in height and no improvement in the condition of the feet or in the child's speech.

The second case occurred in a boy of twelve years, who presented nothing like so typical an appearance. He rarely spoke, and was very slow even in answering such a question as "What is your name?" He was still under treatment, but so far had not shown any striking improvement.

Dr. William Osler, of Baltimore, read a paper on the "Successful Treatment of a Case of Infantile Myxedema with the Thyroid Extract." The patient was three years of age, in appearance a typical cretin, and had been under treatment for more than a year. There was no

enlargement of the thyroid gland. At first the child took an amount corresponding to about one-fourth of a gland in each twenty-four hours. When seen about one month ago it was evident that a remarkable improvement had taken place. The cretinoid aspect had been entirely lost; the flesh was firm and the nutrition much improved; and the mental condition and speech had undergone the most remarkable improvement. Dr. Osler reported a second case, in a cretin nineteen years of age, in which the treatment had been carried out, although not so systematically, and with not very decided benefit.

Dr. W. L. Carr, of New York City, spoke of a case he had seen in which very marked improvement in the mental condition and general nutrition had followed the use of the thyroid extract.

Dr. Forchheimer, of Cincinnati, spoke of a nineteen-year old cretin in whom treatment with the thyroid extract produced such a condition of excitement, almost maniacal, that it was necessary to stop the thyroid extract.

Dr. L. Emmet Holt, of New York City, read a paper entitled "Acute Pyelitis in Infancy." He reported the case of a male child, eighteen months old, that suddenly became ill, and presented a temperature of 103 5°. There was marked pyrexia for about five days, and examination of the urine showed it to contain a large quantity of pus, but no casts. The pus diminished slowly in quantity, and disappeared at the end of about three weeks. Twenty months later, examination showed that the child was in all respects well, and the parents stated that there had been no return of the urinary symptoms.

A second case was a female child, eight months old, in whom the illness began with a chill and a sudden rise of temperature to 105°. The existence of pneumonia was positively excluded. In this case also there was considerable pus in the urine, and it disappeared slowly under the administration of small doses of potassium citrate. This case likewise ran a course of about three weeks, and sixteen months later it was found that the patient had remained free from all urinary symptoms.

In a third case, after the initial chill and the rise of temperature, there was an irregularly remittent temperature which did not yield, notwithstanding the administration of exceedingly large doses of quinin. The spleen was not enlarged. On the fourth day, there being some slight straining and pain on urination, a specimen of urine was obtained, and examination showed it to be strongly acid and purulent. This case extended over a period of about three months, and presented a number of unusual features. It was possible that there was a malarial element in this case.

Dr. Seibert said he thought the first case appeared to be one of cystitis. He would like to know upon what Dr. Holt based the differential diagnosis in this case between purulent cystitis and pyelitis; and also on what he based his diagnosis in the other case between purulent inflammation of the kidneys and purulent pyelitis.

Dr. Osler said that he thought malaria could be excluded when there was no enlargement of the spleen and the symptoms did not yield to quinin.

Dr. Forchheimer said that he had frequently seen cases of low-grade intermittent fever which did not yield to quinin, and he had also found that in cases of malaria the spleen was not always enlarged.

Dr. Holt said that the absence of mucus, the fact that the urine was always acid, and that there was no evidence of vulvo-vaginitis seemed sufficient to exclude cystitis in the first case. The second case might have been malarial. He agreed with Dr. Osler regarding the points in the diagnosis of malaria.

Dr. George N. Acker, of Washington, D. C., exhibited a "mirror writer" in the person of a colored boy ten years of age, whose writing was reversed, so that it could be read when reflected in a mirror. This boy was a premature child and was very delicate during his early infancy. He had many convulsions, which became much more frequent and severe after a fall on the head when he was about two or three years of age. He had also had a persistent chorea. He now wrote with equal dexterity with both hands. There was a history of insanity on the mother's side, and the father was markedly neurotic.

The Association of American Medical Colleges, at its recent meeting at San Francisco

Resolved, That colleges, members of this Association, shall require of all matriculates an examination as follows: 1. An English composition in the handwriting of the applicant of not less than two hundred words; said composition to include construction, punctuation, and spelling. 2. Arithmetic—Fundamental Rules, Common and Decimal Fractions, and Ratio and Proportion. 3. Algebra, through Quadratics. 4. Physics, Elementary —Gage. 5. Latin—An amount equal to one year's study, as indicated in Harkness' Latin Reader.

(This resolution does not apply to students exempt from the entrance examination, as per Section 2, Article III.)

Resolved, That the following classes of students be recognized as entitled to apply for advanced standing in colleges members of this body: *a*. Such graduates of recognized colleges and universities as have completed the prescribed courses in Chemistry and Biology therein. *b*. Graduates and matriculates of colleges of Homeopathy. *c*. Graduates and matriculates of colleges of Eclectic Medicine. *d*. Graduates and matriculates of colleges of Dentistry requiring two or more courses of lectures before conferring the degree of D.D.S. *e*. Graduates and matriculates of colleges of Pharmacy. *f*. Graduates and matriculates of colleges of Veterinary Medicine.

It is provided, however, that the foregoing class of students be required to comply with the provisions of the entrance examination, and to prove their fitness to advanced standing by an individual examination upon each branch below the class he or she may desire to enter.

Resolved, That students graduating in 1899 or subsequent classes be required to pursue the study of medicine four years and to have attended four annual courses of lectures of not less than six months' duration each.

The American Academy of Medicine will hold its nineteenth annual meeting at Jefferson, N. H., on August 29 and 30, 1894. The following papers may be expected:

"The Retrogressives: What Produces Them; Classification," by Bayard Holmes, Chicago, Ill. "Importance of the Study of the Subject to the Profession," by Chas. McIntire, Easton, Pa. "The Provident Dispensary in England," by H. Webster Jones, London, England. Title to be announced, by J. A. Spalding, Portland, Me. "Assistance and Care for the Blind," by Charles A. Oliver, Philadelphia. "Prevention of Blindness," by Benjamin Lee, Philadelphia. "Present Status of Legislation for the Prevention of Blindness from Infantile Ophthalmia," by Lucien Howe, Buffalo. "Senile Dementia and Testamentary Capacity," by J. N. Whittaker, Cincinnati. Title to be announced, by Gershom H. Hill, Independence, Ia. "What Agencies Conspire to Check Development in the Minds of Children?" by J. Madison Taylor, Philadelphia. "The Medical Service of the U. S. Pension-Bureau," by P. S. Conner, Cincinnati. "Physical Training for Delinquents," by Helen C. Putnam, Providence, R. I. "Government Commission instead of State License," by J. D. Kelly, New Haven, Conn. "The Relation of Food-Adulterations to the Dependent Classes," by Henry Leffmann, Philadelphia. Title to be announced, by G. M. Gould, Philadelphia. President's Address. Title to be announced, by F. H. Gerrish, Portland, Me.

Arrangements have been made for a special excursion from New York and Boston and return at reduced rates A choice is offered of an eleven days' excursion, including most of the expenses, or of returning immediately at the close of the meeting, and is open to any one desirous of attending the meeting, whether members of the Academy or not. Any additional information about the meeting or the excursion may be obtained from the Secretary of the Academy, Dr. Charles McIntire, Easton, Pa.

The American Public Health Association will hold its twenty-second annual meeting at Montreal, Canada, September 25, 26, 27, 28, 1894. The following topics have been selected for consideration: "The Pollution of Water-supplies." "The Disposal of Garbage and Refuse." "Animal Diseases and Animal Food." "The Nomenclature of Diseases and Forms of Statistics." "Protective Inoculations in Infectious Diseases." "National Health Legislation." "The Cause and Prevention of Diphtheria." "Causes and Prevention of Infant Mortality." "The Restriction and Prevention of Tuberculosis." "Car Sanitation." "The Prevention of the Spread of Yellow Fever."

Papers are invited upon the following additional subjects: "On the Education of the Young in the Principles of Hygiene." "Private Destruction of Household Garbage and Refuse." "Disinfection of Dwellings after Infectious Diseases." "Inspection of School-children with reference to Eyesight."

The Cholera and the Plague.—It is reported that during the first three days of July there were twenty-one cases of cholera in St. Petersburg, six of which terminated fatally. In the twenty-four hours ending at noon on July 4th, eighteen new cases and five deaths were reported. Eighteen cases and four deaths were reported in Cronstadt between July 1st and 4th. A fatal disease bearing strong resemblance to the plague prevailing at Hong Kong is said to be prevalent in numerous Russian provinces, and has also made its appearance in St. Petersburg, Moscow, and other places. From Brussels it is reported that three cases of cholera with one death occurred at Liége on July 5th. Three cases with one death are reported from Angleur, near Liége, and one fatal case from Jeysille.

Gussenbauer, of Prague, has been placed in charge of the second surgical clinic of the University of Vienna. Czerny, of Heidelberg, after having agreed to accept the succession to Billroth, subsequently declined the appointment through an unfortunate misunderstanding.

The American Electro-Therapeutic Association will hold its fourth annual meeting in New York, September 25th, 26th, and 27th, at the Academy of Medicine. Members of the medical profession are cordially invited to attend.

Southern Medical Review is the name of a new "monthly journal of medicine and surgery," published at Houston, Tex., and edited by Dr. N. J. Phenix.

Dr. V. P. Gibney has been elected Professor of Clinical Surgery in the College of Physicians and Surgeons of New York City.

Dr. B. Meade Bolton has been made Associate in Bacteriology in the Johns Hopkins University.

Addendum.—In the case reported by Dr. J. S. Carpenter in The Medical News of June 23, 1894, p. 700, it should have been stated that the dose of morphin and atropin injected hypodermatically and followed by alarming symptoms was gr. ss. and gr. $\frac{1}{75}$ respectively.

ORIGINAL ARTICLES.

A CASE OF MALIGNANT MEASLES.[1]

BY J. C. WILSON, M.D.,
OF PHILADELPHIA;
PROFESSOR OF PRACTICE OF MEDICINE IN JEFFERSON MEDICAL COLLEGE.

House-epidemic of measles; four cases, of which one was hemorrhagic; at the time of the convalescence of the last of this group, rapidly developing illness of an adult male member of the household, with petechiæ, collapse, violent fever of reaction, continuing stupor passing into coma; death upon the fifth day.—The family in which the case about to be described occurred, in addition to the servants, all of whom escaped, consisted of five persons; the father, thirty-seven years of age, who at sixteen had typical measles at the same time with his sister; the mother, who never had measles; and three children, aged respectively eleven, nine, and seven years.

On March 9th the second child, a girl, had measles, the rash appearing upon the fourth day and the attack running a mild course without complications.

On March 14th the youngest child, a boy, developed the disease, the rash appearing upon the fourth day. The attack proved a very severe one, the temperature on several occasions reaching 105.6° F., and petechiæ in great abundance developing on the second day after the appearance of the exanthem, especially upon the extremities. This case terminated in complete recovery.

The third case was that of the mother, the attack beginning on the 19th, the rash appearing on the fifth day. The attack was severe and attended with pronounced catarrhal symptoms and great prostration.

The rash was first observed upon the oldest child, a girl, on the 25th, the case being remarkably mild and running a short course.

J. H. G., the father of the children, thirty-seven years of age, was a muscular, well-developed man, of medium stature and excellent general health. He had been until early adult life a stammerer, but had by persistent effort overcome this defect of speech. He had also suffered from early childhood from hay-fever, and having failed to obtain permanent relief from local treatment of the nose was in the habit of spending the months of August and September in camp in the forests of Northern New York or Maine. His paternal grandfather died at an advanced age of diabetes; his father at the age of sixty-one of pernicious anemia. Otherwise the father's family was healthy and long-lived. On the mother's side there was a history of gout and migraine. The patient was one of five children, of whom two died in infancy and two survive.

On April 1st the patient appeared to be in perfect health, and incidentally observed that he had never felt better in his life. In the course of the following night he awoke and felt uncomfortable, remarking subsequently that he thought he had an attack of indigestion. On the morning of April 2d he felt indisposed and had a temperature of 100° F. Nevertheless he went out and attended to business engagements. He returned in the middle of the day, complaining of headache, his axillary temperature being 103.5° F. There had been no chill or chilly sensations, no nausea or vomiting. The headache was at this time diffuse and severe. There was neither rigidity nor tenderness upon pressure of the muscles of the back of the neck. The pulse was of fair volume, 100 per minute. There was a slight redness of the anterior half-arches, but no pain on swallowing. Other catarrhal symptoms were absent. At 7 P.M the temperature had fallen to 102.4° F. The headache was less intense; the condition of the throat unchanged; the tongue was slightly coated; the pulse 112, of moderate volume and tension; the face pale. The man now expressed some uneasiness about his condition, and stated that he had never before felt so sick.

It was reported that during the course of the night the patient had twice gotten out of bed for a drink of water. On April 3d, at 8 o'clock, the man was stupid, and could be roused only with difficulty. The surface was cool, bathed in sweat, and the skin was covered with petechiæ. The hemorrhagic spots varied in diameter from 1 to 8 or 10 mm. They were mostly ovoid or circular in outline, but many of the larger ones were quite irregular. They were very abundant and nearly uniformly scattered over the trunk and thighs, but were more thick-set upon the arms and legs, and were especially massed at the wrists, on the neck, and about the temples. A number were visible upon the palms of the hands. In several groups a distinctly crescentic arrangement was noted. There was no hemorrhage from mucous surfaces. The temperature was 100.2° F.

At 11 o'clock the man's condition had become desperate. The temperature had fallen to 99° F.; the skin was cold and clammy, shriveled and inelastic. The pulse was 120, but so feeble as to be counted with difficulty. Upon being roused the patient made monosyllabic replies, and put out his tongue, but had to be again aroused to retract it. Under treatment, which consisted of hypodermatic injections of strychnin, atropin, tincture of digitalis and brandy, the application of external heat, oxygen-inhalations, sinapisms, reaction took place,

[1] Read at the Annual Meeting of the American Pediatric Society at Washington, May 30, 1894.

but stupor bordering upon coma continued. The tongue was dry and glazed. The patient when roused asked for water, which he swallowed with eagerness. Weak milk-punch and liquid beef-peptonoids were from time to time administered. The bowels were constipated, and the urine not being voided catheterization became necessary, and was with some difficulty effected by Dr. Keen. It was thought best to leave a catheter *in situ*. There was no vomiting and no rigidity of the neck. The pupils were of medium size, equal and reactive to light.

At 4 P.M. the temperature was 97.2° F., the pulse 108, the respirations 32.

At 8.30 P.M. the temperature was 98° F., the pulse 108, the respirations 30. The condition of the patient was otherwise unchanged.

During the night, from April 3d to 4th, the temperature rose steadily. At 6 A.M. it was 102.6° F.; at 8.30 A. M., 104° F. It remained high, reaching 105.2° F. at 6 P.M.

During the day a small number of maculo-papules of a faint, dusty-pink color were observed upon the wrists, the side of the face and neck, but not elsewhere. Slight conjunctivitis was present, more marked in the right eye. There was no sneezing and no cough. There was some impairment of resonance, with feeble vesicular murmur and small mucous râles at the bases posteriorly, these signs being more marked upon the right side. The first sound of the heart was feeble. There was occasional delirium of a quiet kind, with snatches of song and low whistling. Upon being roused and interrogated the patient replied that he felt very well. There was slight muscular rigidity, so that the limbs somewhat resisted flexion. The reflexes were preserved, but not increased. During catheterization there was noticed for the first time a rhythmic spasm of the muscles of the right thigh and leg. Blood was taken from a large petechia upon the thorax, by Dr. A. C. Abbott, for microscopic examination and culture.

Toward evening the delirium ceased, and the condition was one of stupor, from which the patient could with difficulty be momentarily aroused. The head was slightly retracted, but could be flexed upon the chest and moved from side to side without difficulty and without eliciting indications of pain. The condition of the pupils was unchanged Risus sardonicus and subsultus tendinum were almost constant.

The urine, diminished in amount, passed away through the catheter, which was retained in position. It was acid in reaction, of a specific gravity of 1029, and contained a small amount of albumin, but no sugar, and no crystals. Upon the examination of several slides there was discovered a single hyaline cast, slightly granular. The bowels had not been moved. The pulse was from 130 to 140, feeble, irregularly intermittent, difficult to count. The cardiac impulse and the first sound of the heart were feeble. The respirations ranged from 38 to 46.

On April 5th the condition was about the same as it had been. The rhythmic tremors observed the day before during catheterization now recurred from time to time spontaneously, or were provoked by movement of the limbs, arranging the bed-clothes, etc. They sometimes affected the muscles of the right leg; sometimes they were confined to those of the left, and sometimes they affected both lower extremities. The upper extremities had only occasionally shown this phenomenon, and then to a very slight extent. The administration of fractional doses of calomel, followed by an enema, resulted in a copious evacuation of the bowels. The temperature remained high, fluctuating between 103.5° and 105° F. The papular eruption observed the previous day upon the face, neck, and wrists had faded.

Shortly after midnight on April 6th there was a large, loose movement of the bowels. The temperature having risen to 105° F., the pulse being 144, the respirations 46, the patient was placed in a bath at the temperature of the room, cooler water being poured over the head and face. The duration of the bath was ten minutes. At its close there was noted a transient lessening of the stupor. An hour later the temperature had fallen to 101.6° F., and the pulse to 130, while the respiratory frequency remained about the same. For some hours the temperature fluctuated between 102° and 103° F. It rose toward morning to 104° F. The stupor deepened, the breathing became more shallow, the pulse more feeble and frequent. The temperature rose to 105.6° F., and at 9 P. M. death occurred.

Rigor mortis was fully established in the course of two hours, at which time there was general discoloration of the abdomen and thighs. An autopsy was not permitted. No subsequent infection arose in the house or in any attendant or visitor.

The treatment during the first day consisted in the administration of antipyrin, gr. ijss, together with caffein citrate, gr. j, at intervals of an hour and a half or two hours. Some four or five doses in all were taken. On the second day the treatment was directed to the condition of collapse, as already indicated. It consisted principally in the administration of ten-minim doses of tincture of digitalis hypodermatically at intervals of two or three hours, with gr. $\frac{1}{30}$ of strychnin sulphate at like intervals, and gr. $\frac{1}{100}$ of atropin on three occasions, and the free administration of alcohol hypodermatically, the application of external heat, sinapisms, and frictions of the extremities. Inhalations of oxygen were given from time to time. The digitalis had no obvious influence upon the action of the heart or the pulse. On the other hand, the hypodermatic injection of strychnin was usually followed by a temporary increase of cardiac force. The inhalation of oxygen had a remarkable influence, which was repeatedly noted, in slowing and deepening the respiratory movements.

When, in the course of the third day, muscular rigidity, tremor, and risus appeared, the question arose as to whether or not they were produced by

the strychnin. This drug had, however, been given in moderate doses and at considerable intervals. Its employment was nevertheless at once suspended. The symptoms referred to continued until the patient became comatose, and were doubtless due to causes entirely independent of the treatment.

The remarkable influence of the bath in lowering the temperature was not accompanied by other favorable manifestations, except a very transient improvement in the mental condition. The temperature began to rise after a short time, and continued to do so until in the course of a few hours it had reached its former level. The bath was regarded by the patient's friends as an unnecessary hardship, and excited their opposition. Partly for this reason, and partly because it was evident from the beginning that the illness would prove fatal, its administration was not repeated.

Dr. Abbott reported as follows:

"I have examined the blood of Mr. G., both microscopically and by culture-methods. Microscopically nothing of importance was detected, beyond a rather high proportion of polynuclear leukocytes and a relatively low number of other lymphatic elements.

"Neither bacteria nor any other forms of parasites were detected. Efforts at cultivation, made both by the ordinary methods and by special anaërobic methods, resulted negatively in all of ten or twelve tubes. One tube only showed a growth, and this a single colony of the ordinary 'skin-coccus.'"

To make the history complete it is necessary to state that a pet dog had been ill for three weeks with so-called chorea, and was chloroformed about the time the first case of measles occurred in the house. Subsequently members of the patient's family raised the question as to the nature of the dog's illness and as to the possibility of the communication of some obscure virulent infection from the animal.

I wrote to Dr. Leonard Pearson, in regard to the illness of the dog, and received the following reply:

"Your favor is at hand, and I take pleasure in giving you the information that you request in reference to Mr. G.'s dog. I first saw the dog (a small female spaniel, about three years old), Sunday, February 25th. At that time there was well-marked chorea of the hind legs, accompanied by great muscular weakness. The animal was in other respects in a normal condition. The pulse was regular, the temperature 101°, the appetite good, etc. The prognosis was unfavorable, because I know from experience that these cases do not respond readily to treatment, although they do sometimes recover. The animal continued to grow worse until Friday, March 9th, when it died. It never had fever; petechiæ were not present at any time, and the only abnormality, beyond the chorea and resulting weakness, was a slight swelling of the nasal mucous membrane. I last saw the animal Thursday, March 8th. At that time it was completely exhausted, and I advised its destruction, as I had previously done on several occasions, but was told that it had been decided to keep the dog as long as it could eat.

It may be that chorea followed distemper, but I am not at all clear on that point, as there is no history of previous illness, with the exception of a passing indigestion; while distemper is a disease accompanied by great prostration and a catarrhal condition of the mucous membranes, with discharges from most of the natural openings, there was no evidence of infection during the time that I had the dog under observation. Even if the animal had suffered from a malignant attack of distemper, which was not the case, I have no reason to think that a person could become infected from such a source. If it were possible, we would undoubtedly hear of numerous cases among kennel-attendants, who frequently have to nurse a large number of puppies with the distemper. The attendant in the dog-hospital at the University would be especially exposed to this danger, did it exist, but I have never heard of a case of the sort, nor have I ever known of an instance in which it was even suspected."

Apart from the general interest excited by instances of malignant infection, this case is chiefly important from the standpoint of diagnosis. We are familiar with such cases in the common acute infections. There are few practitioners of large experience who have not seen instances of malignant scarlet fever, the nature of which in the absence of characteristic symptoms has been evident in the light of the prevalent local or house-epidemic. Cases of this kind are far from uncommon in small-pox. They have occurred very frequently in cerebro-spinal fever, usually at the outset of epidemics. It is of the cases of this variety of epidemic cerebro-spinal meningitis that the learned Stillé has said, in discussing the futility of treatment, that "the first symptoms of the disease are the first phenomena of death."

Cases of malignant measles occur among children in institutions, especially when there is crowding or the conditions are otherwise unsanitary. They are occasionally observed in camps and garrisons, and the malignity of measles when first introduced among a people previously free from it was shown in the great epidemic in the Fiji Islands in 1875.

Harwood,[1] who observed this epidemic, states that the type of the disease was adynamic, and that in this respect it differed markedly from measles among the Anglo-Saxon races. Vital depression was early and marked. Death followed rapidly the first appearance of the symptoms.

William Squire, who published a more circumstantial account of this great epidemic, estimated

[1] S. S. Harwood: Pacific Medical and Surgical Journal, 1875, Vol. vi, pp. 351–355.

that from one-fourth to one-fifth of the native population, or more than 20,000 persons, perished in the course of four months from this disease. Squire[1] says: "One need invoke no special susceptibility of race nor peculiarity of constitution to explain this great mortality." He ascribes it to fear, to bad conditions of living, and a want of care—a view not generally accepted, and not sustained by subsequent events.

But malignant measles in general practice and especially among persons living, as in my case, under the most favorable hygienic conditions, is extremely rare. For this reason, and for others that suggest themselves, especially with reference to prophylaxis against a new infection that might have been accidentally introduced, the question of diagnosis became one of great practical importance. The differential diagnosis had to be made between measles on the one hand and (1) typhus, (2) purpura fulminans, (3) cerebro-spinal fever or (4) variola on the other hand.

1. Of *typhus* there could scarcely be a question. Philadelphia has, it is true, at long intervals been visited by limited local epidemics of typhus fever, occurring usually among immigrants and under conditions of poverty and squalor, but there have been no cases reported for a long time, and the patient had had no communication with persons of those classes in which typhus is likely to show itself. He had, moreover, during the month previous to his sickness, spent most of his time in his own house, occasionally going to a country place for exercise, or to two or three offices in the city where he had business.

2. The possibility of the disease being an unusual form of *purpura fulminans* was carefully considered. Against this, however, several important facts are arrayed, namely: the previous excellent health of the patient, his age, the sudden onset of the attack, the pyrexia, the rapid development of a universal petechial rash, which did not increase either in numbers or in size, the absence, although life was prolonged five days, of bleeding from mucous surfaces, and finally, the faint and limited measly rash which appeared upon the third day.

3. *Cerebro-spinal fever.* Certain of the symptoms suggested a sporadic case of cerebro-spinal fever. These were the suddenness of onset, the violent initial headache, early collapse, hemorrhagic eruption, nervous phenomena, as delirium, stupor, tremor, and rigidity, shallow respiration and faint and arrhythmic action of the heart. But vomiting did not occur, painful rigidity of the muscles of the back of the neck was absent, and there were no evidences whatever of meningeal inflammation. Moreover, the rash observed upon the third day acquires in this connection a diagnostic importance of the highest degree. Why should we go out of our way in search of an explanation of the case when there was in the patient's household an infection to which he had been directly and peculiarly exposed for a considerable time?

4. *Smallpox.* The absence of exposure, so far as known, the absence of anything in the rash like a pock, previous, repeated vaccination, good scars, the character of the petechiæ, which nowhere tended to spread, and the fact that no contagion arose subsequently in the house, negative the hypothesis that the nature of the case was variolous.

The direct diagnosis of malignant measles rests upon the exposure, the faint and limited but distinct maculo-papular rash, the crescentic arrangement of the petechiæ and the febrile movement, active at first, interrupted on the morning of the second day by collapse due to overwhelming toxemia, and re-established upon reaction.

Dr. Abbott's examination of the blood yielded, it is true, a negative result, but this fact does not militate against the diagnosis, as negative results have occurred in a large proportion of examinations of the blood in measles, and the positive results of various observers are as yet far from being in accord. Nor can the fact that the patient had measles in his boyhood be urged against this diagnosis, as unquestioned second attacks occasionally occur.

In this group of five cases there were, then, illustrations of the two forms of hemorrhagic measles described by systematic writers. First, the benign variety, which showed itself in the son. In him the attack was severe but typical in its evolution, the rash showing itself on the fourth day with its usual characteristics, and only becoming hemorrhagic a day or two later, the hemorrhage being confined to the papules and outlasting them for a considerable period, recovery taking place without other unfavorable manifestations. And second, the malignant or fulminant form, in which an overwhelming infection, acting at once upon the nervous system and the blood, deranges the familiar sequence of the phenomena of the disease and replaces the ordinary symptoms by the morbid manifestations of a toxemia of the gravest kind.

This latter form is well described by Louis Starr[1] in the following words:

"Malignant, ataxic, or black measles may occur as an epidemic or sporadic affection, but it is usually the former. There is great prostration; the patient is dull and stupid; the pulse is small, feeble, and frequent; the respiratory movements are difficult and rapid; the rectal temperature is high, often reaching 107° or 108° F., while the hands and feet

[1] Transactions Epidemiological Society, 1880, vol. iv, p. 74 *et seq.*

[1] An American Text-book of Diseases of Children, 1894.

feel cold; the tongue is dry, brown, and thickly coated; epistaxis is often obstinate, and hematuria may occur. The rash appears slowly, imperfectly, and irregularly, assumes a livid, purplish, or blackish hue, and may quickly retrocede; at the same time the skin is thickly mottled with petechiæ. The attack progressing, the pulse becomes so rapid that it can scarcely be counted; there is muscular tremor with muttering delirium, and life terminates in coma or convulsions. After death ecchymoses may be found in the viscera."

In the house-epidemic here described it may be assumed that the infecting principle in all the cases was practically the same. The clinical variations must then be ascribed to constitutional peculiarities and varying powers of resistance in the different individuals attacked.

In this connection it is interesting to note that the grandfather of the patient died of diabetes, the father of pernicious anemia, the patient of malignant measles with rapid breaking down of the blood, and that his son had the benign form of hemorrhagic measles.

THE USE OF METALLIC DISCS AND CYLINDERS IN THE ELECTRIC TREATMENT OF DISEASES OF THE SKIN.

BY JOHN V. SHOEMAKER, A.M., M.D.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND CLINICAL PROFESSOR OF DISEASES OF THE SKIN IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA; PHYSICIAN TO THE MEDICO-CHIRURGICAL HOSPITAL.

MANY diseases of the skin are more favorably and more speedily influenced by the application of electricity than by any other method of treatment. It is by no means, however, a matter of indifference in what form the force is employed. Some affections are most distinctly improved by the use of static electricity; in others, amelioration is brought about by faradism or galvanism, as the case may be; while in some instances an alternation of the faradic and galvanic currents has a more beneficial effect than can be obtained from the restricted use of either of the forms.

Many ingenious appliances have been invented by which the force may be most conveniently and advantageously used in affections of different regions of the body. In the treatment of diseases of the skin I am in the habit of using, with much satisfaction, metallic discs and rollers which can be readily attached to the conductors. These electrodes are nickel-plated and have several important advantages in practical work. The use of metallic plates, discs, or cylinders is a cleanly or aseptic means of applying faradism or galvanism to the skin. The metal can always be cleansed by an antiseptic solution immediately after each operation, and can be washed in boiling water.

Metals are not only cleanly, but they furthermore possess a twofold therapeutic application. The first consists in moderate pressure by the operator. The degree of pressure may be easily regulated and constitutes a valuable therapeutic factor in maladies of the skin. In the second place, galvanism, applied with moderate pressure, has a deeper penetrative action upon pigmentary deposits, inflammatory infiltrations, and neoplastic formations.

The discs employed are of circular shape and about three inches in diameter. The cylinders are about five inches in length. These metallic appliances have been made for me by the E. A. Yarnall Company, of Philadelphia.

When the diseased surface is of considerable extent, the cylinder may be rolled to and fro, the pressure being regulated according to the nature of the case. Upon smaller areas the discs may be left in contact until the patient experiences a sensation of warmth in the skin.

Applied by means of metallic plates and rollers, galvanism relieves painful conditions of the skin and anomalies of sensation; it stimulates absorption and has a parasiticidal influence. Applied in the formative stage of acute inflammations it will very often abruptly arrest their progress. This brief statement of the valuable properties of galvanic electricity is suggestive of its various uses in dermatology.

Dermatalgia, or neuralgia of the skin, gives rise in many cases to extreme pain and in some instances it may involve a large area. In the latter event especially, the application of mild galvanic currents by means of the metallic cylinder has a speedy effect in diminishing the suffering. The constitutional effect of the agent will not infrequently prove of avail in permanently removing the condition upon which the distressing manifestation depends. Hyperesthesia and hyperalgesia, so closely related to dermatalgia, both as regards their mode of origin and the sensations to which they give rise, may be successfully treated in the same manner.

Paresthesia, or pruritus, a more common neurosis than those just mentioned, causes, in many instances, suffering scarcely less intense than acute pain. The peculiarly annoying sensations banish sleep, and the frequent loss of rest may even affect the general health. Paresthesia is particularly atrocious when it attacks the orifice of the rectum or vagina. In consequence of scratching, the skin is often thickened, reddened, fissured, or even eczematous. Very commonly the morbid sensations are experienced simultaneously upon a large portion of the general surface or, as frequently happens, they are suddenly transferred from one to another region. These peculiarities present a serious ob-

stacle to the employment of ordinary methods of treatment. One cannot be constantly anointed, mopped with lotions, or lie indefinitely in a bath. Electricity is, in these cases, a powerful means of relief, not only acting upon the peripheral distribution of the nerves, but also in influencing the state of the central nervous system. Its use may be modified in such a way, also, as to stimulate the activity of the alimentary system, upon some fault of which the paresthesia often depends.

In cases of general itching the metallic cylinder may be used, with excellent results, to subject the affected surfaces to the influence of galvanism. When the seat of disease has been thickened as a result of constant irritation, I often employ with success faradism in alternation with galvanism. The use of electricity has a further advantage in these cases. It quiets the central nervous system and predisposes to sleep, so that the patient who has been tossing upon his bed in torment is once more enabled to enjoy peaceful and refreshing slumber.

Other maladies in which itching is a prominent feature are likewise mitigated by the alternate use of the faradic and galvanic currents. As regards this symptom, eczema is notably to be included in the same category. Itching is one of the most constant symptoms of eczema and attends nearly every stage and form of that disease. At times the distress to which this subjective symptom gives rise is almost intolerable. The manifestation is the most severe in the case of nervous subjects. Electricity, moreover, plays a more important rôle in the treatment of eczema than the mere relief of a symptom, however troublesome. In the chronic form of the disease the skin becomes thickened and hard from inflammatory deposits. The inelastic integument is likely to crack, especially in those parts most subjected to motion. The fissures, once produced, are difficult to heal. The alternate application of faradism and galvanism stimulates the absorbent vessels; the infiltration is gradually removed; the fissures then yield to treatment and the surface returns at length to a normal condition.

The smarting, tingling, burning, and itching of urticaria are allayed by the application of galvanism, which will, not infrequently, bring the attack to an end.

The galvanic current, administered through discs or rollers of metal, is a most valuable therapeutic measure in the treatment of psoriasis. The applications may be made daily, and are certainly the most effectual local means at our command for causing resolution of the thickened patches characteristic of the disease. In an affection so notoriously obstinate as psoriasis galvanic electricity deserves to be prized as a valuable form of treatment. At the same time we should not overlook the advantage of making use of proper medicinal methods for counteracting any toxemic condition that may underlie the cutaneous disease. Galvanism is particularly efficacious in those cases in which psoriasis has its origin in some disturbance of the nervous system.

The sorbefacient power of galvanism has been demonstrated in some diseases that are of yet more inveterate and generally incurable character than psoriasis. In scleroderma the integument is thickened and hardened by an actual increase of organized tissue. The connective-tissue elements and the yellow elastic tissue of the corium are hyperplastic, and in some cases the muscular fibers are also increased. No method promises so much relief in such a serious deviation from the normal type of nutrition of the integument as does galvanism. Clinical experience has demonstrated that galvanic electricity is more potent in this fortunately rare disease than any other method of treatment. The inelastic patches of morphea, also, are more amenable to the same applications than to purely medicinal means. The same method may be used with favorable results in the case of several varieties of new formations, such as keloid and fibrous tumors of the skin, hypertrophied scars and angiomata.

Galvanism diminishes active congestion by a stimulant effect upon the vasomotor nerves and consequent contraction of the vessels. For the same reason it may, when employed with judgment and caution, arrest rapidly the course of an acute inflammation. In erythema it overcomes the dilatation and turgescence of the capillaries; the redness of the skin fades and the transudation is absorbed.

The application of mild galvanic currents has an excellent effect in relieving the itching and smarting sensations of dermatitis due to poisoning by rhus toxicodendron and similar plants. The swelling is at the same time reduced. In erysipelas the method is no less useful. Many surgical procedures, some of them quite elaborate, have of late years been proposed and practised with the view of limiting the spread of erysipelas from its point of origin to other parts of the surface. This very desirable object may often be accomplished by the application of a weak galvanic current, and the metallic cylinder furnishes an excellent means by which it may be brought into contact with the surface. The metallic electrode, being placed in connection with the kathode, or negative pole, is moved slowly around the circumference of the erysipelatous patch, the positive pole being held stabile at the center of the lesion. The strength of the current should not exceed 5 or, at most, 10 milliampères.

In cellulitis good results may be obtained by the same method of treatment. If the case is seen sufficiently early the formation of pus will generally

be prevented. In those other painful and severe affections of the skin and subcutaneous cellular tissue, boils and carbuncles, leading to suppuration and necrosis, galvanism, applied in the manner described, notably diminishes and shortens the inflammatory process and, if applied in the formative stage, has even an abortive effect. The constitutional depression produced, especially by carbuncle, is also combated by the use of electricity.

A mild galvanic current, transmitted through the metallic disc placed over the lesions, checks the progress of herpes. The smarting, burning, and pain are alleviated, the spread of the vesicles is arrested and their drying is promoted. This treatment is equally efficacious in herpes zoster. It checks the development of the vesicles and, furthermore, is of marked utility in relieving the lancinating pain that generally accompanies the disease and that sometimes is very resistant to the influence of drugs. As, in the commonest form of herpes zoster —that which occurs upon the side of the chest, in the course of the intercostal nerves—the involved surface may be of considerable length, the metallic cylinder will be preferable to the disc.

Mild galvanization is beneficial in acne. It abbreviates the duration of the lesions and lessens suppuration. It promotes the resolution of acne-papules and softens and removes the hard lesions of acne indurata. Faradism is also of service in acne, affording relief to the itching and reducing the swelling of the skin. In the different forms of acne—rosacea and alopecia—I have frequently employed these two forms of electricity in alternation. Not infrequently I derive more benefit from their alternate application than from the restricted use of either form.

We have in galvanism an effective method of treating seborrhœa oleosa. A slightly exaggerated activity of the sebaceous glands may merely serve to produce a cosmetic defect, which, however, is capable of causing much distress of mind in its subjects. In some cases greasy crusts are formed and the affection gives rise to itching and burning sensations. The transmission of a galvanic current through the metallic disc in contact with the seat of disease affords marked relief to the symptoms and brings about a healthy condition of the glands.

It has been shown that the lesions of lupus vulgaris may be favorably influenced by galvanism, which causes the nodules to undergo resolution and absorption and stimulates the ulcers to repair.

The dilatation of the vessels, the passive congestion, and the tenderness that persist for a long time after the occurrence of frost-bite may be relieved by alternate applications of the faradic and galvanic currents.

The destructive effect of electricity upon micro-organisms has been utilized in the treatment of some of the parasitic diseases of the skin. There is reason to believe that the bactericidal properties of this force are destined to be more generally employed in dermato-therapy than they are at present. Some of the good results produced by its use in acute and suppurative inflammations may be due to its parasiticidal action. Cases of tinea trichophytina and tinea favosa have been cured by galvanism. The force was, however, employed in a different manner from that described in this paper. Solutions of chemic substances having antiparasitic power were driven into the follicles, ducts, and glands of the skin by the action of galvanic electricity, the sponge-electrode being moistened in the solution and pressed firmly upon the skin.

ORIGINAL ADDRESS.

HIGHER MEDICAL EDUCATION AND THE NEED OF ITS ENDOWMENT.[1]

BY WILLIAM H. WELCH, M.D.,
OF BALTIMORE, MD.;
PROFESSOR OF PATHOLOGY IN THE JOHNS HOPKINS UNIVERSITY.

THE invitation which I received from the Medical Faculty of the Western Reserve University, to deliver an address upon this occasion, carried with it the suggestion that I should speak of higher medical education, and of some of the advantages of liberal endowment of medical education. My choice of subject is in accordance with this suggestion, as well as with my own inclination.

The time has come when the needs of medical education should be brought forcibly before the general public in this country. Medicine can no longer be taught with the simple appliances of former times. The proper teaching of medicine now requires hospitals, many laboratories with an expensive equipment and a large force of teachers, some of whom must be paid enough to enable them to devote their whole time to teaching and investigating. These things require large endowments of money, and cannot be adequately secured simply from the fees of students. If the public desires good physicians it must help to make them.

In this country, for the most part, we cannot look to the State for endowment of medical education, but we must appeal to private beneficence. A few public-spirited and generous men and women have already given practical proof of their appreciation of these facts. With more general and fuller realization of the needs and present condition of medical education, and of the results that can be secured by its liberal endowment, there is every reason to believe that these benefactions will be largely and rapidly increased, and that thereby the condition of medical education in this country shall cease to be a reproach to us. During the last few years our methods and standards of medical teaching have shown remarkable improvement.

[1] An Address delivered at the Graduating Exercises and Fiftieth Anniversary of the Medical Department of the Western Reserve University, February 28, 1894.

What I shall have to say concerning higher medical education will relate to what may be done where there are adequate pecuniary resources outside of the fees of students, rather than to what may be practicable now in this place or generally in this country. The hampered conditions prevailing in most medical schools in this country do not permit the complete realization of the methods and standards of education of which I shall speak. One of the principal aims of this address, however, is to indicate the importance of securing endowments, in order to improve the character of medical education. I do not intend, however, to draw an ideal picture, but only one that is realized in many foreign countries, and which is in measurable distance of accomplishment in several medical schools of this country.

What preparation should a student bring to the study of medicine? It is highly desirable, in my judgment, that he should be liberally educated; that is, he should possess a degree in arts or in science which shall be an index of that knowledge and culture which, apart from any immediate bearing upon professional studies, are recognized as entitling their possessor to be ranked among liberally educated men. Scientific studies have acquired the right to rank with classic studies in affording this liberal culture; but the humanities should have a fair share of attention at this period of education.

The question has been discussed whether or not during the period of collegiate education the student who intends to study medicine should be required to pursue any special subjects, and especially such as bear a direct relation to his future professional studies. The answer to this question seems to me to depend upon the character of collegiate training on the one hand, and of medical training on the other hand. The primary purpose of collegiate education is to furnish a broad basis of mental discipline and liberal culture, independently of direct relation to professional work. Where, as in the old-fashioned colleges in this country, and in the gymnasia and lycées of Germany and France, the student enters college at the age of fifteen or sixteen, and is graduated at nineteen or twenty, it is not necessary or even desirable that the undergraduate student should specialize his work with reference to his future profession. Under these circumstances, which obtain in most foreign universities, at least the first year of medical study is devoted mainly to physics, chemistry and zoölogy, including comparative anatomy.

These are not, however, the conditions which prevail in this country at the present time, where on the one hand the average age of graduation from our best colleges is at least two years later than in Germany and France, and on the other hand, the medical schools do not furnish adequate training in physics, general chemistry, and biology, whereas these sciences are now generally included in the curricula of our colleges. When we consider the fundamental importance of these sciences for the study of medicine, the advanced age of graduation from college, and the special conditions of collegiate and medical education in this country, it seems to me clear that during the period of collegiate study the student intending to study medicine should acquire a fair knowlege of chemistry, physics, and general biology, and to these sciences should be added the study of French and German. Inability to read French and German deprives the physician of personal aquaintance with a large part of the most valuable literature of his profession and makes it impossible for him to keep thoroughly abreast with the progress of medical science and art.

A year's collegiate study, of which practical work in the laboratory should be an important part, is the minimum requirement for such knowledge of physics, chemistry, and biology as should be demanded of medical students upon entrance, and a longer training is desirable. In physics especial attention should be given to mechanical and electric experiments. The student must learn at least the outlines of inorganic chemistry and the elements of organic chemistry, to enable him to study with any degree of intelligence and profit chemic physiology and pathology. In biology he should follow for at least a year a laboratory-course in the structure, life-history, and vital activities of selected types of animal and vegetable life. It is more important that he should acquire certain fundamental concepts concerning the structure and properties of living things, than that he should devote his time to systematic zoölogy. It is impossible to have any adequate understanding of the structure and functions of the human body in health and in disease without a comprehension of the fundamental facts of physics, chemistry, and general biology.

There are certain points which should be clearly understood as regards the requirement that the preliminary education of a medical student should be a liberal one, indicated by a degree in arts or science, and should be made to include a specified amount and kind of knowledge of physics, chemistry, and biology, with a reading knowledge of French and German. The justification for the latter requirement is that, inasmuch as students are kept in college in this country two years longer than in most foreign countries, they should be permitted to pursue during at least the last two years of their course subjects that bear upon the study of medicine, but which, although included in the medical curriculum in foreign universities, are strictly liberal studies, independently of their professional bearings. These sciences preliminary to medical study can be studied and taught better in the college than in the medical school, and, indeed, in foreign universities they are more often pursued by medical students in the philosophic than in the medical faculty. It would be a waste of energy and money to make provision for them in both the medical and the academic departments.

It cannot be truthfully said that the plan indicated need divert the preliminary education from a liberal to a technical and specialized one, for the degree in arts or science will presumably indicate that the student has a liberal education and the special subjects need not be taken up before the last two years of the course. This scheme presupposes that the student will have made up his mind to study medicine in time to include these special subjects in his undergraduate studies. If he has not done so, or if he chooses to exclude them from his collegiate work, he will be obliged to devote at least a year to them after graduation and before beginning the study of medicine. The college-authorities should, however, direct attention at the proper period of the course to the importance of these subjects for those

who intend to study medicine. This plan, moreover, adjusts medical education to existing conditions of collegiate education in this country, without any essential changes in the curriculum of the latter.

The advanced age of graduation from college is a serious embarrassment to higher medical education in this country and has led to the unfortunate result that with the increase in the time required for the study of medicine there has been a falling off in the number of medical students with a college-degree in at least one of our leading medical schools, although it cannot be doubted that the average amount of preliminary education has increased among our medical students.

Various suggestions have been made, especially by the medical faculties of our universities, to remedy this anomalous condition of collegiate education or to adapt it to the needs of medical education. I think that we may assume that the college-course is not likely to be shortened, or that the college will relinquish that part of its development which has made it something between the old college and a university. There is good reason to believe that there are serious defects in our systems of primary and secondary education, and that without lowering the standard of admission better methods of teaching will enable students to enter college at least a year younger than is now the case.

The plan has been adopted in some of our colleges of permitting students to begin their medical studies in the medical department at the beginning of their senior year. This is a plan which, of course, is applicable only when there is a medical school in connection with the college, and involves certain sufficiently apparent difficulties. I think, however, there is much to be said in favor of this arrangement, which permits the student to take up the study of human anatomy, physiology, and physiologic chemistry in his senior year in college, provided he has sufficient preliminary training in the fundamental sciences that have been mentioned. It may, however, be questioned whether the time available for the study of physics, chemistry, and general biology in college is any too long for this purpose, and will permit the addition of human anatomy with dissections, and other subjects that must be a part of the regular medical curriculum. Unless the student has completed the work of one year of the medical course, I do not see the justification of permitting him to shorten by one year the regular medical course because he has a college-degree.

It should be understood that if a medical school requires for admission a year's collegiate training in physics, chemistry, and biology, subjects that are included in the medical curricula of European universities, its period of medical study is, according to European standards, lengthened by one year, the first year being relegated to the collegiate period.

The only medical school in this country in which a liberal degree is required for admission is that of the Johns Hopkins University. Here it is also required, for reasons that have been stated, that the candidate for admission shall be able to read French and German, and shall have had a year's collegiate training with laboratory-work in physics, chemistry, and biology. It is of course impossible for unendowed medical schools to demand anything approaching these conditions for admission. I do not undertake to say that, even were other medical schools so situated that they could demand them, it would be wise for them to do so under present conditions, but it seems to me that there is room in this country for at least a few medical schools with such a standard. Exactly what it is feasible to require as a general standard for admission to medical schools in this country at the present time is a subject which, as already said, I do not consider in this address.

It is true that without a liberal education a man may become a competent physician, and may attain even a high standard of excellence in his profession, but with such education he is better adapted for the study of medicine, he is more likely to succeed in his profession, his social position will be better, and his life will be fuller.

The ultimate and essential aim of medical education is to train persons to treat conditions of disease and injury of the living body. This art, the most difficult and responsible of all human arts, rests upon a foundation of scientific facts relating to the structure and functions of the body in health and in disease. These fundamental facts are comprised in anatomy, physiology, and pathology. Upon the basis of these medical sciences the student is prepared to study the nature of therapeutic agents and their effects upon the body, and to proceed to the study of practical medicine and surgery. The greater part of the time to be devoted to the practical branches must be given to general medicine and surgery, including obstetrics and gynecology, but opportunities must be afforded for acquiring some knowledge of the various specialties. Instruction should be given also in hygiene, legal medicine, and medical history.

To anyone who is at all familiar with the contents, constantly increasing, of these various branches of medical study, it is clear that it is hopeless to attempt to give the medical student a complete knowledge of any one of them. This would require for each subject a period of time at least equal to that available for the study of all.

How long should be the period of undergraduate study in a medical school? In Europe it is nowhere less than four years, and in most European countries it is longer. In Sweden it is nine or ten years, in Spain seven years, in Italy and Holland six years, in Austria, Russia, Portugal, and several universities of Great Britain five years, in Germany four and a half years. In Canada the required period is four years.

According to a statement kindly furnished to me by Dr. John S. Billings, fourteen regular medical schools in the United States either now require, or during the coming year will require, attendance upon four annual courses of lectures in conferring the degree of doctor of medicine. Thirty-seven schools require four years of study, of which one year may be only with a preceptor. Seventy-six require three courses of lectures, and seven require only two courses.

The required period of study in the Medical Department of the Johns Hopkins University, where a full year of collegiate training, with laboratory-work in physics, chemistry, and biology, is required for admisson, is, according to European standards, at least five years.

Four years of undergraduate study in a medical school, each year of study being the usual academic

year of about eight months, are as much as can reasonably be demanded in this country at the present time. This length of time is sufficient, if the student enters with a satisfactory preliminary training, especially if, as is often the case, he supplements the undergraduate course with a year or a year and a half in a hospital, or a year of special post-graduate study.

Only those medical schools that have good laboratory and hospital facilities are warranted in establishing a four years' obligatory course. It would be absurd for some medical schools, with their pathetically meager outfit, to require the student to remain with them four years.

As regards the distribution of subjects in the medical curriculum, the amount of time to be given to each, and the methods of teaching, there is, of course, room for much difference of opinion. I should say that in a four years' course the first two years should be devoted mainly to the fundamental medical sciences, to wit: anatomy, physiology, physiologic chemistry, pathology, including bacteriology, and pharmacology, and that the last two years should be given to practical medicine, surgery, obstetrics, and hygiene, with a limited consideration of the more important specialties. Before entering upon the latter half of the course the student should pass an examination upon the studies of the first two years. The examinations upon both the scientific and the more strictly professional subjects should include practical exercises.

The study of human anatomy will extend through the first two years, and will include in the first year dissections and laboratory-courses in normal histology and embryology. Gross anatomy should be taught mainly by dissections and from text-books. Applied anatomy and special dissections will fall mainly in the second year, and partly may be left, as regards special points, to the supervision of the teachers of the practical subjects.

My preference is for the Continental rather than the English conception of the department of anatomy, viz., that the professor of anatomy should be a scientific man, broadly trained in comparative and human anatomy, not engaged in professional practice, and having under his supervision all that belongs to normal anatomy. He should be well enough paid to be able to give his whole time to his subject, and should have under his charge a well-equipped anatomic laboratory. There is, however, no serious objection to referring the instruction in normal histology and embryology to the physiologic department. Indeed, it is desirable that some consideration of physiologic function should be combined with the instruction in microscopic anatomy.

The subject of physiology, which treats of the normal functions and activities of the body, is of the first importance in medical education. It has attained a higher degree of precision in experimental methods than any other medical science. A good knowledge of physiology is the best corrective to irrational theories and practice in medicine. Physiology has become a highly specialized science, and should be represented in the medical school by a good physiologic laboratory and a teacher who is thoroughly trained in physiologic methods, and can devote his whole time to the subject. It should be taught by demonstrative lectures, text-books, and laboratory-courses. Laboratory-courses in physiology, although important, are hard to arrange, on account of special difficulties inherent in the subject. They do not, therefore, play so predominant a rôle as in the teaching of anatomy and pathology. The study of physiology will continue throughout the first year, and may extend into the second.

The chemic side of physiology has become so large and specialized and is so important in medical education that chemic physiology, or as it is generally called, physiologic chemistry, has come to be recognized as a distinct department in many medical schools. There are advantages in keeping this branch of study in the physiologic laboratory. Whether or not it is made subordinate to physiology or is established as a separate department will depend largely upon the special interests of the professor of physiology and the kind of man selected to teach physiologic chemistry, as is illustrated by the different arrangements in this regard in the German universities. The teacher should be a thoroughly trained chemist and also familiar with physiology and medicine.

Physiologic chemistry means much more than what is usually taught in our medical schools as medical chemistry, which includes little more than the chemic analysis of certain fluids of the body for diagnostic purposes. Anatomic structure and physiologic function depend to a very large extent upon chemic composition. Our knowledge of the processes of nutrition, digestion, and secretion, both in health and in disease, has been greatly advanced in recent years by the work of physiologic chemists. The microörganisms that cause infectious diseases do injury largely by their chemic products, and many of the questions relating to infection and immunity can be answered only by the aid of chemic investigation.

"I cannot understand," says Hoppe-Seyler, as quoted by Chittenden, "how at the present day a physician can recognize, follow in their course, and suitably treat diseases of the stomach and alimentary tract, of the blood, liver, kidneys, and urinary passages, and the different forms of poisoning, how he can suitably regulate the diet in these and constitutional diseases, without knowledge of the methods of physiological chemistry and of its decisions on questions offering themselves for solution and without practical training in their application."

Physiologic chemistry in the broad sense that I have attempted to indicate should receive proper consideration in a medical school. Its physiologic and pathologic bearings should be emphasized. It should be taught during the first year largely by laboratory-courses. It is important, as already stated, that the student should enter with sufficient preparation in inorganic and general organic chemistry to enable him to proceed at once to the study of chemistry in its physiologic relations.

Pathology I would place as a principal subject in the second year. This subject embraces general pathology, gross pathologic anatomy, and pathologic histology, and with it can be appropriately associated bacteriology. The student should be taught the proper methods of making post-mortem examinations and of recording the results in protocols. The teaching should be by lectures, text-books, and to a very large extent by demonstrations and laboratory-work. As abundant use as possible should be made of the demonstration of fresh patho-

logic specimens, which at the same time can be studied in fresh microscopic sections. Bacteriology can be taught in a laboratory-course of two or three months.

It seems to me advantageous that the systematic study of pathology should precede that of the clinical subjects. The latter, however, should be accompanied with the demonstration of pathologic specimens and with courses in clinical microscopy, so that the pathologic knowledge and experience of the student will be kept fresh and will be increased during the last two years of the course. The pathologic laboratory, which it is desirable to have in close connection with the autopsy-room, should be in charge of a professor who gives his whole time to the subject, and it should be well equipped for work in all departments of pathology, including bacteriology. An active and well-organized pathologic laboratory can have a very important influence for good upon the life and scientific activities of a medical school and hospital.

Pharmacology, or the study of the nature of therapeutic agents and their behavior and effects in the living body, has become of late years a more scientific subject by closer association with the methods of physiology, chemistry, and experimental pathology in investigating the action of therapeutic agents upon patients and experimentally upon animals. Our knowledge has become greater and more precise as to the behavior of drugs within the body, and as to their action upon the circulation, digestion, secretion, and other processes and functions of the body. A large number of new drugs are constantly brought to the attention of the profession. Of these Dr. Delafield has said: "Many of the new drugs are of much help to us; we can do useful things to-day that we could not do some years ago, but it must be admitted that we can also do harm in a greater variety of ways." There is a tendency to greater simplicity in prescriptions and a more extensive employment of other than pharmaceutic methods of treatment.

The teacher of pharmacology should be trained in the modern methods of pharmacologic research, and he should have under his charge a laboratory in which the student may acquire by practical work some of this knowledge.

The teaching of the application of therapeutic agents to the treatment of disease should fall to a large extent upon the teachers of clinical subjects.

As the time of the student will be so fully occupied with anatomy, physiology and physiologic chemistry, and the corresponding laboratory-work during the first year, the study of pharmacology may be left to the second year, where it seems appropriately to belong.

When we are told that hygiene is the study of the causes and prevention of disease, and that its aim is to preserve and to promote health, it would seem as if this subject were of the first importance in medical education. But when we consider what a complete department of hygiene really means, and what are the problems with which the modern hygienist has to deal, such questions as the sanitary condition of houses and communities, the contamination and purification of drinking-water, the disposal of sewage, the adulteration of food, the dangers of certain occupations, the study of vital statistics, matters relating to sanitary legislation, it is apparent that undergraduate instruction in hygiene for the medical student must be more restricted than the theoretic and practical importance of the subject would seem to indicate. Still it is important that some instruction in this subject in the form of demonstrative lectures should be an obligatory part of the course, and among the optional subjects of the last years of the course, laboratory-work in hygiene may be well included. Many licensing and examining medical boards require that the candidate shall be examined in hygiene. The student should learn at least enough of sanitation to know that there are many sanitary subjects upon which intuitional judgments are of no importance, and that as regards these only the opinion of a sanitary expert is of any value.

Practical training in bacteriology falls in many foreign universities to the department of hygiene. This must be taught, but it makes little difference whether it be taught in the pathologic or in the hygienic laboratory, although personally I prefer its association with pathology. Each of these laboratories must be supplied with facilities for bacteriologic work.

We owe to Pettenkofer, of Munich, the first organization of a complete hygienic laboratory, and this has served as the model for many others. The Munich laboratory has been one of the ornaments of the University, and has been of inestimable value to the city in bringing about such great improvements in public sanitation that typhoid fever, the most significant index of the hygienic condition of a city, has virtually disappeared, whereas it was formerly so prevalent that visitors were warned against it. The development of bacteriology and its association with hygiene has led during the last decade to the establishment of a department of hygiene in most German universities. Fortunate that medical school, and especially fortunate that city, in which there is a well-equipped and active laboratory of hygiene. So beneficent may be the working of such a laboratory to the general community, that this is a department for which the support of the public could be reasonably solicited. Medical officers of public health should of course be especially trained in hygiene, as is required in England.

The last two years of the medical course should be devoted to the study of the strictly professional, the so-called practical, subjects. The previous study of anatomy, physiology, physiologic chemistry, pathology, and pharmacology has been the best preparation for the pursuit of the practical branches of medicine, and it should be recognized that the place of these sciences in the course and the amount of time devoted to them are justified on the ground that they furnish an important part of the training of practitioners of medicine and surgery.

The teaching of the strictly professional subjects must be eminently practical and cannot be satisfactory without sufficient clinical material. The student should have the opportunity of frequently observing patients in the hospital-wards, in the operating-room, and in the dispensary, and of seeing methods of treatment and their results. He should come into personal contact with patients, should examine and study them, should take their histories, follow the course of disease, and report upon the cases. Attendance upon clinical lectures cannot take the place of this direct, personal, continuous observation of cases of disease. Students during their last years should enjoy some of those advantages of a

hospital-service that have usually in this country been reserved for the fortunate internes. It is especially as regards arrangements for such personal clinical work for the students that our overcrowded medical schools are at a disadvantage as compared with schools of smaller attendance. Hence Billroth, in each of the fifteen editions of his *Lectures on General Surgical Pathology and Therapeutics*, has admonished students: "Flee therefore in the beginning of your clinical studies the great universities."

The attempt to cover the whole ground of the theory and practice of medicine and of surgery in courses of didactic lectures is rapidly giving place to systematic clinical teaching and recitations from text-books. Practical courses in methods of diagnosis and in the use of clinical instruments of precision are essential. Clinical laboratories have become a valuable adjunct to the department of medicine, and should afford to the student practical courses of instruction relating to such subjects as the examination of sputum, blood, gastric contents, secretions, etc.

Surgical practice has profited even more than medical practice by the scientific discoveries of recent years. The general principles of surgical procedure have become much more simple and straightforward than formerly, and the results of their application are in the highest degree satisfactory. In the allotted time the student can acquire a fair knowledge of these principles by lectures, clinics, and practical courses, but only study and practice after graduation can make him a surgeon.

It seems to me that a considerable part of the instruction on certain subjects in general pathology—as, for example, inflammation and tumors — often assumed by the professor of surgery, should be left to the professor of pathology. I venture to say also that, according to a distinction in titles, and at least to some extent in usage, in many American medical schools the implication that the main professorship of surgery is one primarily of didactic teaching and the subordinate professorships are those of clinical teaching is singularly unfortunate.

Greater use than is customary can be made of experiments upon animals in teaching some matters pertaining to surgery, such as certain details in surgical technique, the healing of wounds of different parts of the body, their behavior under the influence of antiseptics, of foreign bodies, and of other circumstances, etc.

I shall not speak on this occasion of the instruction in obstetrics.

It is impossible for the medical student in his undergraduate days to acquire any thorough knowledge of the various specialties in medicine. Too much should not be attempted in this direction. The study of some specialties should be obligatory, that of others may be optional, but the medical school should furnish opportunities for the study of all.

I should like to see in every medical school a course of lectures upon the history of medicine. It adds to the liberal culture of a physician to learn who have been the great discoverers and the master-minds in medicine, what has been the condition of medicine at different periods of the world's history and among different peoples, what doctrines have prevailed, and by what means progress has been achieved.

As regards the methods of teaching medicine, the keynote at the present time is object-teaching. For nearly two centuries traditions derived from the University of Leyden have largely controlled systems of medical instruction. Purely didactic lectures, designed to cover the whole ground of medicine and surgery, acquired undue prominence in the scheme of instruction. We now believe that greater emphasis should be laid upon the study of text-books, and that the student should be brought into direct, personal contact with the objects of study. The scientific subjects must be taught largely by laboratory-practice and the practical subjects in the clinic.

While laboratory-teaching is of the highest importance, it nevertheless seems to me possible to give to it too exclusive prominence, although I am reluctant to say this in view of the prevalent defects in opportunities for laboratory-work in most of our medical schools. There is no medical school in this country which is able at present to furnish all of the laboratory-instruction which is to be desired.

It should be borne in mind that laboratory-methods are extremely time-taking and are not adapted to teach the whole contents of any of the medical sciences. It is, of course, hopeless to attempt to demonstrate practically all of even the more important facts that the student should learn. Laboratory-work is especially valuable in training methods of thought and observation and in developing the scientific spirit. The knowledge derived from actually seeing, touching, experimenting, is of course more real and impressive than that which comes simply from reading and from listening to lectures, but the student whose knowledge of a subject is derived exclusively from laboratory-courses is likely to lose his perspective in details, to acquire only fragmentary knowledge of a subject, to fail to comprehend the general bearing of observed facts, and not to acquire the general principles and systematic conceptions which are essential. Laboratory-courses may be conducted so that some of these defects are minimized, and these points would perhaps not need emphasis if the time available for the study of the different subjects were unlimited, but a large number of subjects must be taught in a comparatively short time. Laboratory-work should be accompanied and supplemented by the reading of text-books and by lectures. The details of every subject must be learned to a large extent from books. Didactic lectures have their place in presenting the broad outlines of a subject in a systematic way and in emphasizing, as only the living voice can, essential and salient points. Such lectures can be made also demonstrative by drawings, charts, specimens, experiments, the use of the magic lantern and the exhibition of original monographs and works not readily accessible to students.

Recitations upon the subject-matter of lectures, of text-books and of laboratory-courses are especially important. They bring the teacher into personal contact with the student, they secure systematic reading and study, they bring to light the difficulties and misconceptions of the student, and afford opportunity for their correction.

As I have already said, only a relatively small part of medical science and art can be taught during a period of four years. This necessitates a careful selection of the subjects to be taught, of the amount of time to be

given to each subject, of the sequence in which the subjects are to be taken up, and of the methods of teaching. There must be a careful adjustment of the various parts in their relation to the whole, and in their relation to the ultimate objects of medical education—the training of practitioners of medicine and surgery. No subject should be taught as if the student were to become a specialist in it. The teaching must be simple and clear. The problems that are of most interest to the teacher are often not those with which the student need concern himself. The majority of students will not have opportunity or inclination after graduation to devote much time to a continuation of the study of anatomy, physiology, and pathology, and these subjects, being of fundamental importance, should therefore be taught with much thoroughness.

It is important that the student should carry away from the medical school a certain mass of positive knowledge. It is still more important that he should acquire some measure of medical wisdom and of the scientific spirit, and that he should have that methodic training in observing and in drawing logical conclusions, and that familiarity with instruments and methods of examination which will enable him to continue independently his education, to follow and incorporate the new discoveries in medicine, and critically to judge and to make the most of his own observations. Medical education is not completed at the medical school; it is there only begun. Of the various subjects in a medical course, the fundamental medical sciences are especially those which afford to the student this methodic training, and are calculated to develop habits of accurate observation and to stimulate scientific interest in the practical side of his profession. The medical art is becoming more and more the application to practice of medical science. It is the development of medicine along the lines of a biologic science that renders it increasingly attractive to liberally educated men with inclinations to scientific pursuits.

The medical school should afford encouragement to special and advanced work. The few who have the capacity, the inclination, and the time to become investigators and teachers should find there stimulus and opportunity. It should be a place where medicine is not only taught but also studied. It should have a share in the advancement of medical science and art by encouraging original work, and by selecting as its teachers those who have the capacity and the training for such work. The heads of departments should be supplied with a sufficient number of assistants, so that their time need not be given wholly to teaching. These assistants ought to be paid. In most laboratory-courses there should be at least one demonstrator for every fifteen students. In the selection of assistants preference should be given to young men who desire to carry on original work, who have aptitude for such work and for teaching, and who would like to follow an academic career.

The sketch that I have drawn of a medical school is not intended to be an ideal or impracticable one. It is simply what is realized in many foreign universities and what the best opinion in this country desires. It is not to-day realized in any medical school in this country, although a few are approaching this standard.

That a medical school as completely equipped as I have indicated does not exist in this country is not due to any lack of appreciation on the part of medical teachers of its necessity, but is due to the fact that such a school cannot exist without large endowment, either from private philanthropy or from the State, and none of our schools has sufficient endowment for this purpose.

A properly equipped and organized medical school, with all of the necessary laboratories and a sufficient number of the right kind of teachers, is an enormously expensive affair, far more expensive than any other professional school. The most pressing need of our medical schools to-day is thoroughly equipped laboratories in charge of well-trained teachers and investigators who can give their whole time to their special work. The salary of such a teacher as head of a department ought to be not less than from four to five thousand dollars per annum. There should be six of these laboratories, to wit, of anatomy, physiology, physiologic chemistry, pathology, pharmacology, and hygiene. It is better to place bacteriology with pathology or hygiene, than to make of it a separate department.

The suitable construction and equipment of these six laboratories will cost at a moderate estimate from two hundred and fifty to three hundred thousand dollars. From eight to ten thousand dollars is a moderate estimate of the amount needed to cover the average yearly cost of each of these laboratories for salaries of professors, assistants, janitors, and for current expenditures. I should say that, including the fees of students, the interest of not less than $1,200,000, at 5 per cent., would be required to support a completely equipped medical school in this country. This sum does not, of course, include the amount needed for the support of hospitals connected with the school.

I have been kindly supplied by a friend connected with the Prussian Government with a statement of the amount of money bestowed yearly by the Government upon each of the medical institutes in the different Prussian universities. This amount does not include the salaries of the professors in charge of the institutes, but only the salaries of assistants and servants and the sum available for current expenses. I am permitted to publish only the total amounts and not the salaries of individuals.

The annual dotation by the Government for each of the following medical institutes in the University of Berlin for the purposes specified is: For the first anatomic institute, 40,690 marks; for the second anatomic institute, 11,430 marks; for the physiologic institute, 47,746 marks; for the pathologic institute, 24,450 marks; for the pharmacologic institute, 17,202 marks; for the hygienic institute, 18,500 marks; for the first chemic institute, 26,440 marks; for the second chemic institute, 18,435 marks. The Prussian Government, therefore, expends annually, outside of the salaries of professors, a little over fifty thousand dollars to support the laboratories of anatomy, physiology, pathology, pharmacology, hygiene, and chemistry in a single university. About three times as much money is given by the Government to the support of the laboratories as is devoted to the salaries of the professors, but these salaries are largely, often many times, increased by the fees of students. In

Germany the expenses of living and of the purchase of laboratory-supplies are less than in this country.

Medical education in this country has until recently been left to its own devices. Only within recent years has it received any aid worth speaking of from private philanthropy or the State, save the indirect aid from the establishment of hospitals and dispensaries.

The greatest impulse for the endowment of higher education in this country has been religious zeal. Contrast for a moment the endowment of theologic study with that of medical study. According to the forthcoming *Report of the Bureau of Education*, for proof-sheets of which I am indebted to the kindness of Mr. Harris, the Commissioner of Education, there were in the United States in 1890–91 only five endowed chairs in medical colleges, and not a single one of these south or west of Philadelphia. It may, I think, be questioned whether all or even any of the five chairs were adequately endowed. On the other hand, there were 171 endowed chairs of theology, many of these being in the West and South. According to the report of the same bureau, as quoted by Dr. Bayard Holmes, the productive funds in the hands of medical schools, both those connected with and those independent of universities, in the United States was, in 1889, $249,200; while, at the same time, there were in the hands of schools of theology productive funds to the amount of $11,939,631. In 1892, these figures were, for medical schools, $611,214, and for theologic schools, $17,599,979. In 1890–91, out of a total of $1,466,399 given to institutions for professional instruction, 63 per cent. was given to theologic schools and 17 per cent. to medical schools. Medical departments of State universities received, in 1892, State aid amounting to $40,500; technologic schools received State aid to the amount of $747,504. When one considers that there are more than twice as many students of medicine as of theology, and that medical instruction is much more expensive than that of theology, and requires costly laboratories, the contrasts afforded by these figures are startling.

The Report of the Commissioner of Education comments as follows upon these statistics and similar ones relating to legal education: "There can be no doubt of the propriety of private philanthropy endowing theological study, nor of the State's enterprise in supporting technical and pedagogical studies, but it is difficult to discover why such consummately practical and important topics as law and medicine should be neglected by private benevolence or public caution. It seems to be conceded that unendowed instruction in law or medicine will be just as poorly given as unendowed instruction in theology or pedagogy. Yet we find instructors in both these sciences, though necessarily State-supported on the Continent of Europe, in America left to live upon the meager diet of tuition-fees."

Higher medical education, no more than any other form of higher education, is self-supporting. A number of reasons might be specified to explain this singular neglect of medical education as an object of private endowment or State aid. I shall not consider these reasons here. Many of them pertain to conditions that have changed or are changing. The tide has already turned, and "the old order changeth, yielding place to new." The doom of the medical college responsible to nobody, without hospital or laboratory facilities, has sounded.

"Unto everyone that hath shall be given, and from him that hath not shall be taken away even that which he hath."

The needs of medical education have begun to be recognized by high-minded and public-spirited philanthropists, such as Johns Hopkins, Vanderbilt, Mary Garrett, and your own John L. Woods. Such benefactors have "linked their names to those imperishable things" which make the most enduring monuments of a republic. I was particularly impressed by Mr. Adams' statement in his memorial address upon John L. Woods in this place, last October, that Mr. Woods' generous benefaction to this college was chiefly determined by "the fact that medical education had never been a favorite object of benevolence, while the improvement of medical education was really of the greatest importance."

In conclusion, let us not forget that a university or a medical college may have large endowments, palatial buildings, modern laboratories, and still the breath of life not be in it. The vitalizing principle is in the men —both teachers and students—who work within its walls. Without this element of life, this bond between teacher and taught, these things are but outward pomp and show. But let these greater opportunities receive the breath of life from the inspiration of great teachers and they then become the mighty instruments of higher education and scientific progress.

CLINICAL MEMORANDUM.

A CASE OF ANGINA LUDOVICI.

By G. H. STOVER, M.D.,
OF RATON, COL.;
LATE RESIDENT PHYSICIAN IN THE ARAPAHOE COUNTY HOSPITAL, DENVER, COL.

THE following case occurred during the visiting service of Dr. J. W. Exline, of the medical staff of the Arapahoe County Hospital, during my residence there:

Peter F., sixty-six years old, was admitted August 10, 1893, with the symptoms of an incipient submaxillary abscess of the left side. In the afternoon of the 11th he complained of sore-throat during my absence and was given tr. guaiac. ammon. by another resident. The soreness increased, and by evening there was slight dysphagia. Examination showed a little swelling of the left anterior pillar of the fauces; considerable saliva was being secreted. The man had not received any calomel. The conditions continued about the same until the evening of the 12th, when, on my evening round, I found him suffering from dyspnea, not very marked. Examination showed that the swelling on the left side of the throat had extended and presented more of an edematous than an inflammatory appearance.

Upon the advice of Dr. Exline, he was given ice to hold in his mouth, and ice was applied to the side of the neck. A little later I saw him again and the dyspnea was alarming. He could not lie down, but was sitting up gasping for air; his lips were dark and his face expressive of the greatest anxiety and agony. Another examination was made, showing the left tonsil, soft

palate, and walls of the pharynx to be greatly swollen; and there was dangerous edema of the glottis, from which he was in imminent danger of suffocation. The mucous membrane of and about the pharynx and the tonsil was not hyperemic or injected, and there were no signs of exudate or false membrane upon it; neither were there any ulcers upon the tonsils.

I ordered ten grains of calomel at once, and instructed the nurse to spray the throat every fifteen minutes with a solution of tr. ferri chloridi, ℥xxx to the ounce of water; meanwhile, as I was unable to reach the laryngologist by telephone, I prepared to perform tracheotomy should the embarrassment of respiration continue. The spray was thus used some five or six times, with remarkable effect, as the breathing soon became much easier and the edema less. The spray was then used every half-hour for a few hours, and the remainder of the night every hour. At frequent intervals the man was given whiskey and milk (the naso-esophageal tube to be used if necessary), and this, alternated with eggnog, was continued throughout the next day. On the morning of the 13th there was only slight dyspnea and the calomel had acted thoroughly. The spray was then used every two hours, later every three, and finally omitted.

By evening there was noticed on the floor of the mouth (not in the cheek, as in noma) a good-sized necrotic patch, having a slight odor.

Hydrogen dioxid was frequently applied to this, with the result of limiting the spread of necrosis and almost destroying the odor. This necrotic tissue detached itself, and was expectorated at times during the next few days. The submaxillary inflammation did not go on to abscess-formation. The man was gradually put upon regular diet, was given iron and quinin in tonic doses, and rapidly recovered from his prostration. He was discharged September 2, 1893.

While the case here reported differs somewhat from the rather vague accounts of some authors, I believe that the diagnosis, which was based mainly upon Strümpell's[1] description, is correct.

The prompt action of the rather strong solution of iron certainly obviated tracheotomy.

MEDICAL PROGRESS.

The Supra-renal Gland and its Relation to Addison's Disease.—AULD (*British Medical Journal*, No. 1741, p. 1017) details some interesting facts elicited in the course of a study of the supra-renal gland, and calls attention to the extremely vascular character of the inner cortical layer, contrasting strongly with the delicate, pearly-looking tissue of the medulla on the one side and the opaque, yellowish, external portion on the other. The blood seems almost entirely collected in this zone; the intra-vascular pressure is considerable, as indicated by the welling forth of the fluid that takes place after section. Further examination shows that the cells composing this layer are more or less pigmented, highly so in some cases, but faintly so in others. The existence of the pigmented cells has long been recognized, but their significance has not hitherto been understood. Sections reveal the fact that large numbers of red blood-corpuscles make their way into these cells, and are to be found in their interior in all stages of regressive metamorphosis, from the completely formed cell downward. Apparently by a chemiotactic action certain of the red corpuscles are selected and attracted within the phagocyte-cells. They can be seen passing inward, and at first cannot be distinguished in any respect from those in the vessels outside. Gradually they assume a greenish-brown coloration, and thereafter begin to break up into larger and smaller particles. The nucleus of the phagocyte is usually much obscured by the pigment-particles, but it is large, and together with the protoplasm may show signs of formative activity. The opinion is expressed that at least one of the functions of the supra-renal gland is the destruction of a certain class of effete red blood-corpuscles. In the medulla three kinds of cells can be made out: (1) glandular columnar or polyhedral cells, faintly eosinophilous, and with frequent, very large, round or oblong nuclei; these are regularly arranged in the meshes of the reticular network; (2) highly branched corpuscles, with peculiar staining reactions and absolutely non-eosinophilous; these seem to be modified nerve-cells; (3) ganglion-cells proper, which both cluster round large nerves that pass straight through the cortex, and likewise exist in isolated fashion in the reticular meshes. It is assumed to be the office of the medulla to test the quality of the blood, which, so far purified by filtration through the pigmented zone, passes through the medulla before it enters the circulation; certain appearances lead to the suspicion that the medulla is concerned in the further reduction of effete substances. The blood, after passing through the medulla, has the characters of arterial oxygenated blood. Viewing the supra-renal gland as an excretory or depurative organ the symptoms of Addison's disease may be ascribed to an intoxication resulting from the retention of excrementitious products, whilst the pigmentation of the skin is due to the circulation of certain products of the decomposition of hemoglobin. The cells of the cortical zone of the gland are but moderately eosinophilous, and their nuclei readily absorb logwood. Although the acini are usually entirely filled with cells, under favorable circumstances a considerable central lumen may be seen to be filled with secretion—an appearance resembling that found in the anterior lobe of the pituitary body. This secretion is carried away by lymphatics to minister to certain needs of the organism.

Fatal Hemorrhage from Rupture of an Aneurism of the Hepatic Artery.—SCHMIDT (*Deutsches Archiv für klinische Medicin*, B. lii, H. 5 u. 6, p. 536) has reported the case of a woman, some forty years old, under observation with a diagnosis of gall-stones, who, five weeks before death suffered from a moderate gastro-intestinal hemorrhage, a few days later from a second, together with slight jaundice, a third three weeks before death, and finally a fourth, copious bleeding, terminating fatally. Upon post-mortem examination, in addition to the profound general anemia, a false aneurism was found involving a branch of the hepatic artery, and rupture of which had caused death. There were numerous inflammatory adhesions in the right hypochondrium, involving the hepatic flexure of the colon, the great omentum, the duodenum, the gall-bladder, and the inferior surface

[1] Text-book of Medicine, Am. ed., 1892, p. 326.

of the liver. In the midst of the adhesions were a number of small abscesses, none of which, however, communicated with the gall-bladder. Both large and small intestine were filled with blood, which had gained entrance through three openings of communication between the duodenum and the gall-bladder. At each of these openings in the bladder lay a gall-stone, and the three stones fitted closely together. The cavity of the gall-bladder was dilated, while its wall was in places destroyed. The viscus contained also a false aneurism occupied by a large clot of blood, and communicating by an abnormal opening between the gall-bladder and the hepatic duct with a branch of the hepatic artery. The wall of the duct was ulcerated, and its lumen was dilated in the neighborhood of the perforation. The liver contained a large number of small foci, from yellowish-brown to dark-green in color, with softened centers, and containing pus-corpuscles, liver-cells, and granular detritus. These were found to represent altered inter-acinous biliary passages. Some of the biliary ducts were dilated, and in places surrounded by cellular infiltration. Two forms of microörganisms were found: principally streptococci and short rods in smaller proportion. The parenchyma of the liver was in places lost, as a result of increase in the interstitial connective tissue.

Death from Convulsions following Rupture of the Stomach.—O'FARRELL (*Lancet*, No. 3690, p. 1243) has reported the case of an apparently healthy, fairly strong boy, nearly thirteen years old, who while playing became cold and suffered with headache. The boy drank some tea, but would eat nothing, and was given a saline and put to bed. Vomiting took place twice during the night, and by morning the child was no better. The saline was repeated and was followed by vomiting. The complaint of headache persisted, and the mother gave the boy five grains of phenacetin, and in an hour and a half repeated the dose. An hour and a half after this the child suddenly began to scream and had an attack of the most violent convulsions, affecting all of the voluntary muscles. This paroxysm was followed in a short time by another, and the fits increased in frequency and intensity for an hour, when death took place. On post-mortem examination the abdomen was found full of matter similar to that which had been vomited during life and consisting of partly digested food mixed with bile. On the posterior wall of the stomach was a rent three inches long, around which was a large area of inflammation, while the neighboring tissues were soft and pulpy. The cavity of the stomach was empty; the esophagus and tongue were normal. The other organs were structurally perfect, but greatly congested; there was no peritonitis. Histologic examination disclosed a condition of fatty degeneration of the muscular fibers around the rent in the wall of the stomach.

THERAPEUTIC NOTES.

Arsenical Urethritis.—CHALKE (*Indian Medical Record*, vol. vi, No. 8, p. 237) has reported the case of a man who came under observation on account of a urethral discharge of three days' standing, without assignable cause. There had been no sexual intercourse for several months. The meatus urinarius was slightly inflamed; the discharge, which had been mucoid at the outset, was now muco-purulent. The urine was high-colored and its evacuation was attended with scalding. The man had had an attack of gonorrhea six years before, but subsequently there had been no difficulty with the genito-urinary apparatus. No constitutional or mechanical cause for the condition could be elicited, but on inquiry it was learned that the man had for two weeks been taking five minims of arsenical solution thrice daily, containing a total of about a grain and a half of white arsenic. Further investigation disclosed the presence of other symptoms of arsenical intoxication, *e. g.*, slight conjunctivitis, with suffusion and smarting of the eyes, slight edema of the lids, dry cough, irritation of the throat and nose, painful cramps, colicky pains in the lower portion of the abdomen, irritation of the rectum, painful defecation, urticaria, and general prostration. The arsenic was at once withdrawn, and diluents and demulcent drinks directed, together with an alkaline mixture. Improvement was immediate and rapid, despite the fact that stimulants were given, and in the course of two weeks the man was quite well.

The Treatment of Pulmonary Tuberculosis with Petroleum.—Having observed that laborers about the petroleum-wells of Roumania were free from pulmonary tuberculosis, PELLISSIER (*Bull. gén. de Thérap.*, 18. liv., t. cxxvi, p. 416) was led to the use of filtered crude petroleum, administered in capsules, in the treatment of the cases of pulmonary tuberculosis that came under his care during a period of two years, and describes the results as surprising. The cough soon ceased, then the sweats; appetite and sleep were restored; the pulmonary lesions receded; the breath smelled strongly of petroleum; but the digestion was not deranged. The patients were also made to breathe air that had been passed through petroleum. Administration of petroleum by the rectum was tried, but proved unsuccessful.

For Pulmonary Tuberculosis CROCQ (*Internationale klinische Rundschau*, 1894, No. 21, p. 745) recommends the administration of ergot or ergotin. The former may be given in the form of the fluid extract, in doses of from half a dram to a dram or more, and the latter in doses of from half a grain to four grains or more, several times daily. Not only is hemoptysis thus controlled, but expectoration is diminished, the sense of oppression is relieved, and the general condition is improved.

For the Hemoptysis of Pulmonary Tuberculosis DAREMBERG (*La France Méd.; Memorabilien*, xxxviii, 3, 153) recommends, in addition to the usual measures employed, the application of ice to the testicles or the labia majora. There is felt a sudden, painful temporary sense of pressure, and the hemorrhage ceases. If the bleeding recurs the application may be made twice daily or continued for five minutes at a time.

For Amenorrhea.—

R.—Hydrarg. chlorid. corrosiv. . . gr. ¾.
Sodii arseniat. . . . . gr. j.
Ferri sulph. exsic. . . . . gr. xxx.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 21, 1894.

POSSIBLE CAUSES OF CHRONIC AILMENTS.

CHANGES affecting the health and the comfort of communities often take place so slowly and so insidiously that they are unnoticed until detected by some shrewd investigator or until some catastrophe attracts widespread attention to them. An instance of the first method was presented several years ago, when DR. D. D. STEWART, by making a careful inquiry into some cases of chronic disease that had seemed inexplicable to other physicians, elucidated the fact that chrome-yellow was being largely used by Philadelphia bakers as a substitute for eggs, and was causing much chronic poisoning. STEWART discovered nearly one hundred cases—many fatal—originating from two shops. Sudden developments of typhoid fever are constantly occurring in all parts of the world, and indicating previously unsuspected sources of danger in water and milk.

It is inadvisable to imagine causes of disease, yet sanitarians should not be oblivious to the manner in which the manufacturing industries are being modified by invention and discovery, or to the fact that such modifications are guided almost entirely by financial considerations, the effect on public health and happiness being allowed no influence, except when the injury is too flagrant to escape notice. In this manner, for instance, artificial colors have been steadily substituted for the natural colors in articles of food and drink. Very few manufacturers (there are, it is true, some honorable exceptions) have ever investigated the wholesomeness of anilin-red, methyl-orange, and eosin before using them in food-products; few dairymen have thought it worth while to inquire if the preservatives they employ are unwholesome; nor have brewers cared to learn anything of the physiologic effects of beer containing saccharin, salicylic acid, or substitutes for hops and malt.

It is not impossible, therefore, that certain chronic ailments of obscure nature may arise from depression of the vital functions by some such unnoticed abnormal conditions, perhaps hardly reaching the grade of chronic poisoning. The extended contamination of canned goods, as shown by the investigations of the United States Department of Agriculture, was noticed some months ago in THE NEWS, and the possibility of the production of chronic ailments by this contamination then suggested.

Numerous other forms of food-adulteration, intentional and accidental, may be suspected, and among these may be mentioned the now widespread use of imitation-butter. Few persons appreciate the extent to which this substitution occurs, especially during the season when butter commands a high price. Much has been said about the wholesomeness of oleomargarin, but apart from the fact that it is certainly less readily digested than butter and less appetizing, it has been recently learned that it is subject to admixture with dangerous ingredients. That it is artificially colored has long been known, but it has generally been assumed that the colors used were only those usually employed by butter-makers—annatto and turmeric—and considered harmless. It has been shown, however, by recent analyses that at least one coal-tar color—methyl-orange—is now largely used, and as we are ignorant of the effect of long-continued small doses of this body, it is obvious that we have here a source of danger; nor is there any guarantee that the oleomargarin-manufacturers may not without notice or inquiry substitute a more harmful color if a cheaper or otherwise more satisfactory one be found.

Attention has been called to a still more dangerous adulterant, namely, paraffin. The chemists of at least one State experiment-station report this discovery, and there can be no doubt of the harmfulness of such addition. Paraffin is entirely indi-

gestible, and must interfere with the digestion of any fat with which it may be mixed. If this admixture be general, as may easily be the case, it will surely give rise to chronic digestive derangements.

Another source of chronic ailments, especially involving the nervous system, may be suspected from the extensive use of water-gas. This product has won its way into favor on the basis of cheapness alone, and many large cities have adopted it for general consumption. In spite of the statements of experts engaged by the makers, water-gas is far more poisonous than gas made from bituminous coal. This difference is almost entirely dependent on the presence in the former of a large percentage of carbon monoxid, one of the most insidious and deadly gases with which we are acquainted. Leaving out of question the cases of acute poisoning, which have added materially to the number of accidental deaths in all places in which water-gas has been introduced, it is worth considering if much injury to health is not occasioned by the continual leaking of the gas in quantities not sufficient to produce marked symptoms. House-fittings are rarely perfect, and although the smell of illuminating gas is often a means of warning of its escape, individuals may become accustomed to a slight odor of it, and fail to notice the leak. The active ingredient of water-gas is cumulative, and the constant inhalation of air containing only minute amounts of it must establish a condition of ill-health difficult of diagnosis. One often hears of persons who are sensitive to "sewer-gas." In reality there is no such specific gaseous product, but illuminating gas frequently finds its way into drains and sewers, and may thus get into houses, as well as through direct leakage. The possibility of such slow poisoning will make us thankful that the applications of electric heating and lighting are destined at no distant day to render gas an antiquated agent in the household.

EDITORIAL COMMENTS.

Elevation of Temperature as a Symptom of Paralysis Agitans.—A frequent, though not invariable, symptom of paralysis agitans consists in the occurrence of a sense of flushing and heat, often attended with perspiration. Although considerable attention has been devoted to the thermometry of paralysis agitans, there is a lack of concordance of view as to whether either the general temperature or the temperature of the tremulous parts undergoes change. Among other things it has been thought that the movements of the affected parts most likely give rise to some increase in the bodily temperature and a corresponding sense of heat. Some interesting observations on these mooted questions have recently been made by FUCHS at the clinic of Nothnagel at Vienna and are detailed in a communication in the *Zeitschrift für klinische Medicin*, Band xxv, Hefte 3 u. 4, p. 321. Among twenty-six cases of paralysis agitans he found nine that presented periodically recurring elevation of temperature, which disappeared rather rapidly after several hours' duration, the highest figure reached being 102.9° F. In cases in which a subjective sense of warmth was present it was found that there was also elevation of temperature. In one case, simultaneously with the subjective sensation, a difference was observed in the temperature in the axillæ and in the elbow-flexures, being 0.5° to 0.7° higher in the left axilla than in the right, although the right upper extremity was but little shaken and the left scarcely, if at all. The frequency with which this elevation of temperature may be observed in the course of paralysis agitans would thus seem to place it among the symptoms of the disease. Further, the curious observation has been made that in some cases a sense of chilliness has been present in conjunction with a depression of the temperature. In some cases, too, profuse perspiration occurs independently of elevation of temperature. These several manifestations are suggestive of involvement of thermic and vasomotor centers in the lesions of the disease.

Acute Miliary Tuberculosis of Pharyngo-laryngeal Type.—To the four types of acute miliary tuberculosis hitherto described—(1) a typhoid type, in which the symptoms of constitutional infection predominate; (2) a broncho-pneumonic type, in which the predominant symptoms are referable to the respiratory apparatus; (3) a meningeal type, presenting symptoms of inflammation of the cerebral meninges; and (4) an intermittent type of protracted duration—CATTI (*Wiener klinische Wochenschrift*, 1894, No. 24, p. 438) would add a fifth, which he designates the pharyngo-laryngeal type. This, like the meningeal type, occurs especially in children. It is very uncommon, and from the symptoms of laryngeal obstruction to which it gives rise may be mistaken for diphtheria. The affection first manifests its existence by greater or less difficulty in deglutition. On examination the uvula, the soft palate, the epiglottis, and the ary-epiglottic folds will be found swollen, edematous, reddened, and at times ecchymotic. At the same time there occurs an abundant eruption of partly gray, transparent, and elevated tubercles, and partly yellowish, not prominent, tubercles. The cervical and accessible thoracic lymphatic glands may be hyperplastic, and the action of the heart accelerated. The pulmonary percussion-resonance will be unaltered, while auscultation reveals the evidences of laryngeal obstruction. The temperature may not be altered. A fatal issue may result in the course of two or three weeks amid the symptoms of cardiac weakness, dyspnea, and cyanosis, or the duration may be protracted. It is possible that this form of miliary tuberculosis is not so rare as it appears to be, and that some cases of supposed diphtheria of the larynx of long duration and terminating fatally from heart-failure are actually cases of the laryngo-pharyngeal form of miliary tuberculosis.

The Inhalation of Oxygen in Opium-poisoning.—The usefulness of potassium permanganate as an antidote in the treatment of opium-poisoning may, in view of the evidence presented, be admitted. Upon what this antagonistic action depends has, however, not yet been demonstrated, though it is reasonable to assume that the oxidizing quality of the potassium salt plays a prominent rôle in this connection. This supposition would, in some measure at least, seem to be supported by the fact that the permanganate has also proved useful in the treatment of phosphorus-poisoning, cyanid-poisoning, and snake-bite. Further confirmation of this view appears to be afforded by the recent experience of Merry (*Lancet*, No. 3692, p. 1372), who reports a desperate case of opium-poisoning in which inhalations of oxygen seemed to act as the determining factor in bringing about recovery. The victim, a male, thirty-two years old, had, three hours before coming under observation, taken of a preparation of variable composition an amount supposed to represent about eight grains of morphin. The man was unconscious, cyanotic, and breathing stertorously about fifteen times per minute. The corneal reflex was abolished, and the pupils were small and inactive. Flagellation, cold affusion, the use of the interrupted current, the vapor of strong ammonia, and subcutaneous injections of ether failed to bring about reaction. The respirations were labored and had fallen to eight per minute, and the pulse had become almost imperceptible. The cyanosis suggested the use of inhalations of oxygen, and these were forthwith instituted, pure undiluted gas being employed. In the course of twenty minutes the face had regained its normal color, the respirations were fuller, easier, and more frequent, and the pulse had become perceptible and regular. The patient was still stupid, although there was a slight response to corneal irritation. After an interval of half an hour the inhalation of the gas was resumed, with further marked benefit. Consciousness returned, and after the repetition twice of the inhalations after intervals of three-quarters of an hour, the point of danger seemed to have been passed. The man remained drowsy during the day, but did not relapse into stupor. He made a perfect recovery. The suggestiveness of this experience is entirely obvious, and the safety and innocuousness of the method must surely commend it to favorable consideration and intelligent trial in suitable cases.

REVIEWS.

An American Text-book of Gynecology, Medical and Surgical, for the use of Students and Practitioners. By Henry T. Byford, M.D., John M. Baldy, M.D., Edwin Cragin, M.D., J. H. Etheridge, M.D., William Goodell, M.D., Howard A. Kelly, M.D., Florian Krug, M.D., E. E. Montgomery, M.D., William R. Pryor, M.D., George M. Tuttle, M.D. Edited by J. M. Baldy, M.D. Philadelphia: W. B. Saunders, 1894.

We believe that this book is a valuable addition to the literature of gynecology. The writers are progressive, aggressive, and earnest in their convictions. They represent the best thought of the younger generation of medical men in this branch. What faults the book has indeed are the faults of youth. There is some evidence of hasty writing and careless editing. Opinions are often expressed in more dogmatic style than the same writers will employ, perhaps, later in their lives, and there is occasionally an apparent lack of studiousness in the preparation of the articles. To illustrate in part our meaning: Amputation of the clitoris is recommended "on account of . . . . interference with coitus, etc., particularly when occasioning trouble in childhood" (p. 165).

The labia seem to have been the editor's or the proof-reader's chief orthographic stumbling-block. There is repeated mention of *labum minus*, *labum majus*, and the right *labia majora*, and this too as legends under illustrations. In the section on malpositions of the womb, the dogmatic assertion is made that "no attempt should ever be made to replace or otherwise interfere with a uterus which is bound in its displaced position (*sic*) by adhesions," a dictum to which men of experience will not unqualifiedly subscribe. The writer, in fact, seems not to have the courage of his own convictions, for he describes minutely the methods of doing what he strongly condemns.

The illustrations are exceedingly good for the most part. A few are in very questionable taste. Just as much could be taught by outline drawings of postures for examination and operations, as by photographs of nude women. In one or two sections the illustrations appear superfluous. The picture of a man washing his hands might be placed in this category.

In spite of these few imperfections the work, we repeat, is valuable. Its most useful field will be among general physicians. No book of composite authorship can ever be the best text-book for the medical student. There is in all such books an average of excellence. If any one of the individuals whose articles are above that average had written the entire work, it would be a better book than it is.

Human Bones of the Hemenway Collection of the U. S. Army Medical Museum. By Washington Matthews, J. L. Wortman and John S. Billings, Surgeons, U. S. Army.

This elaborate production is a reprint of a memoir from the publications of the National Academy of Sciences. It includes the results of investigations of North American Indian skulls obtained by an expedition which was fitted out in 1887 with funds supplied by the liberality of Mrs. Mary Hemenway, of Boston, for exploring certain ruins in the valley of the Gila River in Arizona. All the facts are set forth in the most interesting manner by Dr. Billings in an introduction, the bulk of the pamphlet being written by Drs. Matthews and Wortman. The whole constitutes a bulky quarto of one hundred and thirty-five pages, containing over three hundred carefully executed figures. It is not often that the publications of the National Academy of Sciences can be appropriately reviewed in the columns of The Medical News, but that this essay can be so reviewed is evident when we reflect that medical men are never indifferent to the facts of human anatomy and the physical condi-

tions of the human race. Nothing but praise can be awarded Dr. Matthews, who has written the greater part of the memoir, for his conscientious and laborious researches. That it was not expected from him that he should frame a very striking essay on craniometry is conceded. In the present state of the subject nothing is so absolutely uninteresting as craniometry. As to deductions Dr. Matthews is wisely silent. Craniometry has no deductions to give us worthy of the name.

We look in vain for conclusions respecting the previous work of Drs. Billings and Matthews on composite photography as applied to the cranium. Dr. Wortman's essay on the hyoid bone shows that the body of the bone was almost entirely free, and that the separate pieces of which the hyoid arch is composed were seldom united in a single bone even in the most aged individuals. This is a curious fact, and in our judgment is not explained on an hypothesis which is based on the use of the hyoid bone in speech.

We agree with the stricture of Dr. Matthews on the attempts to define the "German horizontal plane." We have studied at least one skull in which such a line would compel the face to so tilt as to bring the orbits in a position not unlike that of M. Scheuchzer's famous fossil. One would readily pronounce such a specimen to have belonged, if not to a *homo diluvii testis*, at least to a *homo theoscopos*.

A Manual of Minor Surgery and Bandaging. By Christopher Heath, F.R.C.S., Surgeon to the University College Hospital, etc. 12mo, pp. 389. Philadelphia: P. Blakiston, Son & Co., 1894.

A book in its tenth edition, and one which has now had an existence of over thirty years, needs no recommendation—it speaks for itself. This, the last edition, embodies the latest teachings as regards antiseptics, and is therefore more valuable than its predecessors.

The introductory chapter upon the relation of the house-surgeon to the other hospital-officers is particularly excellent, and might be read with advantage by many attending surgeons. It is particularly strong in recommending careful attention to detail, and seeks to impress upon the surgeon that no detail, no matter how trifling, should be *infra dig.* if it enhances the comfort of the patient or favors the progress of the case. The manner of procedure for the collection of court-fees in police-cases illustrates the practical character of the work in a phase of medical practice in which the novice is uninitiated. The preference given to ether as an anesthetic, while not thoroughly English, strikes the American favorably. All the sections are well written, and the book deserves the success it has always received.

Society of the Lying-in Hospital of the City of New York (Midwifery Dispensary). Medical Report, 1893. New York: Martin B. Brown, 1894.

This report covers a period of fifteen months, and gives statistics of 2583 cases, the largest number of which were treated in the Dispensary. A "Statistical Synopsis," by J. C. Edgar, gives a clear *résumé* of the work done, together with an analysis of various clinical features. The report contains also an elaborate article on "Fever in the Puerperal Woman," by S. W. Lambert and H. McM. Painter; a paper entitled "A Modification of the So-called Credé's Method of Expressing the Placenta," by J. W. Markoe, and a report of "Two Cases of Symphysiotomy," by J. C. Edgar. In addition to formal reports by the pathologist, embryologist, orthopedic surgeon, and bacteriologist, there is an interesting illustrated article entitled "Studies in the Development of the Alimentary Canal," by D. H. McAlpin, Jr.

SOCIETY PROCEEDINGS.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twentieth Annual Meeting, held in Washington, D. C., May 30 and 31, and June 1, 1894.

First Day—May 30th.

Dr. B. Sachs delivered the President's Address. He said that from the scientific point of view clinical medicine and neurology are one and inseparable. The diseases that the neurologist is called upon to recognize and to treat are such that he must necessarily maintain a deep interest in the affections of the heart, of the liver, of the stomach, and surely of the kidneys. He cannot afford to neglect the lungs, nor even the bladder. He is asked, perhaps a little too frequently, to consider the condition of the generative organs, and he must be even better versed than the surgeon in the anatomy of nerves and muscles. The eye, the ear, and the nose have claims upon him. The entire organism is his daily concern, although he may claim to be more intimately acquainted with the structure and functions of the nervous system than with those of any other part.

It is nothing new to think of the ganglion-cell as the nutritive center for the white fiber connected with it, and to know that this white fiber is prone to undergo disintegration if separated from its nutrient cell; but it is new to learn that the entire nervous system is made up of such units of nerve-structure, consisting of a nutritive cell, of the white fiber that emanates from one process of this cell, and of its termination in brush-like fashion. It is new, too, that these units are connected with one another not by direct contact; that the terminal arborizations approach one another without coming into contact, and that these neurons connect the white and gray matter, and pass freely from one to the other, or may exist even within the gray matter alone. If the nutrient cell is destroyed, or if its influence over the fibers connected with it is interfered with, the death of this neuron is the natural result.

Dr. Samuel Ayres, of Pittsburg, read a paper entitled "Myxedema Treated with Sheep's Thyroid." It was particularly advised that at the outset small doses be administered—from one to three grains of desiccated powder in capsules or tabloids once or twice daily, and gradually increased to five grains three times daily, if required. Large doses at the outset have been frequently followed by dangerous symptoms.

The paper was chiefly devoted to suggestions as to the possibilities of the preparation in certain diseases non-myxedematous, and careful trial was recommended in selected cases of acute dementia, mania, melancholia,

epilepsy, chorea, tetanus, anesthesia, and erysipelas; but its indiscriminate employment was strongly discouraged.

DR. STARR, of New York, presented five photographs of patients with myxedema, in three of whom unmistakable improvement was shown. He had used various preparations of the gland, but there were serious objections to many of them. He had of late made satisfactory use of the cheapest preparation on the market, which is put up in the form of tabloids, each containing five grains of the extract. He was often consulted on account of the mental symptoms which were in many instances prominent in this disease. He had frequently observed melancholia with suicidal tendencies. In eight there were symptoms of dementia. He had found the preparation of use in neuroses of the menopause. Among a number of cases of akromegaly only two seemed to be benefited. The headache was relieved and a feeling of *bien être* was produced. His experience with thyroid gland in paralysis agitans, epilepsy, and progressive muscular atrophy was negative.

DR. GEORGE W. JACOBY, of New York, spoke of the difficulties in the diagnosis of true myxedema, and reported a case and presented photographs of a child aged fourteen. There was evidence of muscular dystrophy in the lower extremities. He thought that further experience might show a relationship between these two affections.

Dr. E. D. FISHER, of New York, thought that the use of thyroid extract should be confined to the treatment of myxedema. There was no rational indication for its administration in other diseases.

THE PRESIDENT dissented from this view, and believed it was but fair to try this medicine empirically, as we were not as yet familiar with the true function of the thyroid gland.

DR. F. X. DERCUM, of Philadelphia, reported a case successfully treated by the extract.

DR. L. C. GRAY, of New York, stated that all animal extracts had a similar temporary effect. A number of cases of myxedema had relapsed. He had used the thyroid extract in only one case, with the usual good result.

DR. LEONARD WEBER, of New York, said there was not a single case on record that had been cured.

In one case under his observation, the result was remarkably good. Relapse is likely to occur unless the remedy is continued. He believed that greater and more permanent relief could be obtained by surgical means.

DR. WALTON, of Boston, mentioned a case which improved after the use of only five grains three times a day.

DR. J. ARTHUR BOOTH, of New York, read a paper entitled "The Thyroid Theory in Graves' Disease; Two Cases treated by Thyroidectomy." The following conclusions were presented: 1. It is by no means decided that a mere excess of the thyroid secretion is the sole and essential factor in Graves' disease; but as microscopic examination has demonstrated an enormous hyperplasia of the secreting structure, it is certainly reasonable to suppose that these changes must have some profound effect both on the quantity and the quality of the secretion. 2. If altered structure and not size is the test of the disease, then thyroidectomy should be considered even in those cases in which there is little or no enlargement of the thyroid. 3. Cases of Graves' disease may be entirely cured by thyroidectomy. How this is brought about is not clear as yet. It may possibly be by one of three ways, viz.: a diminution of the functional activity of the gland-substance; a relief of the stretching and irritation of the sympathetic nerve-fibers; or, finally, the removal of pressure.

DR. J. J. PUTNAM, of Boston, said that in one English case reported, the patient seemed to be cured after the use of thyroid extract. He spoke of two patients treated by operation; one was improved and the other died. In both the pulse was excessively rapid. He thought it better to operate early, and not to wait until the heart's action became seriously impaired.

DR. J. MADISON TAYLOR, of Philadelphia, had used thyroid extract in Graves' disease without any perceptible improvement. He spoke of a case occurring in a child two years of age.

DR. W. J. MORTON, of New York, believed that patients had been cured by the use of electricity. He had often seen recovery after three or four months' treatment. He preferred this to any other method.

DR. DERCUM thought it difficult to explain the favorable result occurring after operative measures, and mentioned an instance in which the gland was exceedingly small.

DR. W. A. HAMMOND, of Washington, asked if Dr. Morton had used any other remedy in conjunction with electricity. He had been accustomed to diminish the amount of fluids taken and to give digitalis or hyoscyamin, with satisfactory results.

DR. MORTON replied that he used electricity only.

THE PRESIDENT thought that many cases were curable, and referred to the case of a young woman in whom the disease developed rapidly after a sudden fright. She improved after prolonged rest in bed, subsequently married and gave birth to a healthy child, and completely recovered from her symptoms of Graves' disease.

DR. BOOTH, in closing the discussion, said that the alleged danger from the operation is not borne out by statistics. In his case the patient did well. Galvanism had been faithfully used for seven months without satisfactory results.

DR. FREDERICK PETERSON reported a case of exophthalmic goiter cured by thyroidectomy.

Improvement began immediately after the operation. Shortly after the operation there was diminution of the tremor. The exophthalmos was lessened. The subjective symptoms had disappeared. The tachycardia grew less and less. Five years after the thyroidectomy there was no proptosis whatever, no tremor, no tachycardia, no thyroid swelling, and in fact the patient was well, and had been able to carry on her hard work steadily ever since. The only remains of the trouble is a somewhat rapid pulse, which varies from 90 to 100.

DR. G. W. JACOBY and DR. F. SCHWYZER, of New York, read a paper entitled "Experimental Investigations on the Physical and Chemical Action of the Galvanic Current upon the Living Organism." Recognizing that our scientific comprehension of the electro-dynamic curative action of electricity has been obstructed by the direction as well as the manner in which electro-physiologic work has thus far been car-

ried out, it was hoped that this obstruction could be met by the study of the chemic and physical actions of the galvanic current upon the simplest form of the organism, the living cell. With a view to answering the question: "Does the galvanic current produce any discoverable changes, physical or microchemic, in the single cells of the body?" a series of experiments upon animals (frogs, rabbits and guinea-pigs) and man was undertaken. The certain and positive results thus far obtained were: 1. That by passage of the galvanic current the red blood-corpuscles under the influence of the positive pole swell up and become increased in size, while under the influence of the negative pole they become crenated and shrunken. 2. That two animals being fixed back to back, and a current passed through both from chest to chest, the entire blood in the animal acted upon by the positive pole will contain more than 20 per cent. less alkali than that of the animal which has been exposed to the influence of the negative pole.

While it is believed that the majority of cells in the human body are influenced by the cataphoric action of the galvanic current, it cannot be stated whether or not the physiology of the cells is thereby altered, and to what extent; on the other hand, the decrease of the alkalinity of the blood by means of the current must have a very great influence on cell-life. This is shown by other experiments made upon spermatozoa. This influence consists in the production of a marked functional activity in the neighborhood of the kathode, on account of the slightly increased alkalinity, and reduced functional activity at the anode in consequence of decreased alkalinity.

DR. W. J. MORTON said that as for the results obtained, attributed to cataphoric effect, they seemed to be subversive of what is usually believed and taught, for it has thus far been accepted that the tissue at the negative pole had its fluidity increased, while that at the positive pole had its fluidity decreased.

Again, as to the action of the galvanic current in producing acidity of tissue at the positive-pole region and alkalinity at the negative, he welcomed the experimental evidence that this effect extended widely into the intrapolar region, and thus influenced the irritability of tissue as an anelectrotonus and katelectrotonus. This physical explanation of physiologic states had first been made by Von Humboldt, who attributed the increased response to the excitation of the negative pole to the increased alkalinity produced in an already alkaline tissue by that pole, and the decreased response to the positive pole to the fact that that pole produced an acid reaction. Dr. Morton would go further than this, and had already suggested as an explanation of the increased response to the positive pole in the reaction of degeneration of Erb, that the muscle degenerating had an acid reaction, and therefore responded most vigorously to the acid, viz. the positive pole.

As to alkalinizing the blood electrically, we might perhaps do this better by alkalies administered by the mouth, but we could not by drugs do what Dr. Jacoby had done and render a tissue less alkaline or more acid. Therefore the local action of electricity in this respect could not be otherwise effected.

DR. WILLIAM C. KRAUSS, of Buffalo, N. Y., presented a Neurological Percussion-Hammer. In appearance the hammer resembles the ordinary percussion-hammer, such as is employed more especially on the Continent, and particularly in France and Germany. It is, therefore, primarily a hammer, and for the neurologist may be used for testing the tendon and muscular reflexes, and for percussing the spine and head. The handle, being made of hard rubber, becomes warm on friction, while the head, being made of metal, remains always cold, thus affording the means for examining for thermo-anesthesia. The cap on the small end of the hammer-head is removable, and exposes a triangular-shaped spear about one-sixth inch long. The other end of the head has the rounded rubber-point, thus furnishing a sharp and dull point for examining for anesthesia. The spear is divisible, one-half remaining fixed in the hammer-head; the other half slides upon a scale graduated in millimeters and inches, forming part of the handle of the hammer, making an excellent esthesiometer. On replacing the cap, and removing the cap at the large end of the hammer, a camel's-hair brush is exposed, giving a soft and the metallic end a hard surface for examining sensation. Thus we have in one instrument nearly all the apparatus necessary for making an examination of a nervous case.

DR. J. MADISON TAYLOR, of Philadelphia, showed a neurological percussion-hammer, devised seven or eight years ago, and which has been in constant use in Philadelphia ever since. The instrument was described and illustrated in an article by Dr. Weir Mitchell in THE MEDICAL NEWS, January 23, 1888. The value of this little instrument resides in the fact that it is very useful, both in its special function of eliciting muscular reactions, knee-jerks, etc., for which it is particularly adapted, and also as a percussion-hammer to explore the chest, which purpose it serves unusually well.

It consists of a triangular piece of soft rubber, about an inch and a half on the base and two inches on the perpendicular of an equilateral triangle. It is held at its middle part by a band of metal surrounding it, and the handle is a direct extension of this band, all made in one casting. The original instrument had the handle upon the edge, which then left the general outline of a hatchet or Indian's tomahawk. Since then this handle is sometimes placed upon the middle plane of the rubber piece, the handle then dependent from this center giving the appearance of a hoe or an adze.

The important factor is that the rubber is quite soft, is rounded on the edges, and is about the thickness of the human finger, which it is devised to simulate. In striking a blow upon a tendon the rounded edge, very like the surface of an ordinary finger, comes in contact with the tendon, as, for instance, that of the knee, and the impact is comprehensive, strong, but painless. The pointed end is about the size and shape of the end of a finger, and is likewise comfortable in contact and efficient in eliciting muscle-jerks and reactions upon the surfaces, or is also useful in reaching for deep tendons, as the biceps-tendon, etc. Again, this surface is comfortable when the finger is used as a pleximeter. Indeed, a hammer is often much better than a striking finger, because the quality and direction of the blow can be much more exactly governed, and the general weight and size of this little instrument has been found most satisfactory in this particular.

DR. V. P. GIBNEY, of New York, read a paper entitled "Non-Operative Treatment of Metatarsalgia." He offered as a subtitute for excision of the distal end of the fourth metatarsal bone or the branch of the peroneal nerve, a boot constructed on a Spanish last, with a heel a combination of an English and a French heel. The boot thus built transfers the weight from the ball of the foot to the plantar region just back of the ball of the foot and to the heel and that portion of the shank just anterior to the heel. The chief point insisted on was a snug fit around the instep shank, and a rather loose toe-portion. A number of successful cases were reported.

DR. CHARLES K. MILLS, of Philadelphia, had been in the habit of recommending a shoe similar to that advised by Dr. Gibney. Some cases, however, cannot be relieved by any form of shoe, as a neuritis may have become established. Operative means would then become necessary.

DR. PUTNAM considered it of value to make a carefully adjusted opening in the inner sole of the shoe.

SECOND DAY—MAY 31ST.

DR. W. J. MORTON, of New York, presented some microscopic slides showing the new neuroglia-stain of Weigert. The neuroglia-fibers are stained blue, while the nerve-elements are either not stained at all, or at least very faintly. The medullary sheaths do not accept the stain, and thus the field is left clear for the differentiation of neuroglia-fibers.

DR. MORTON also read by title a paper entitled "A Case of Multiple Neuromata, with Exhibition of Microscopic Sections of a Large Neuroma removed from the Ulnar Nerve."

The tumor developed upon the ulnar nerve about half way between the elbow and the wrist, and was about the size of a hen's egg. Cutting down upon the mass with a view of severing and suturing the nerve, if necessary, or of dissecting out as far as possible its strands, the tumor was found lying quite free, except for a few thread-like adhesions within a capsule, and the nerve traversed this capsule from end to end in five separate bundles. It was, therefore, possible to enucleate the tumor and replace the nerve-strands without the slightest injury to the latter. The tumor was a myxo-fibroma.

DR. GUY HINSDALE and DR. J. MADISON TAYLOR, of Philadelphia, read a paper on "Crossed Knee-Jerk," based on studies of over one thousand cases of nervous disease observed at the Infirmary for Nervous Diseases, Philadelphia, and the Institutions for Feeble-Minded Children at Elwyn, Pennsylvania, and Vineland, New Jersey. By the term crossed knee-jerk is meant that when the patellar tendon is struck the opposite leg is instantly made to approach its fellow; the phrase "in knee-jerk," or "contra-lateral knee-jerk" may also be used. The movement observed in the limb opposite to that of which the patellar tendon is struck is not an extension of the leg so much as an adduction of the thigh (vastus internus and crureus). The best attitude for eliciting the movement is by seating the subject at ease in a chair, with the body erect, and the knees ten or twelve inches apart, with the knee-joint at rather an obtuse angle, the feet being advanced a few inches. The phenomenon is observed in a small proportion of normal persons, and in from 20 to 30 per cent. of the cases coming to a clinic for nervous diseases. It is distinctly proved not to be due to a communicated shock or jar to the pelvis by reason of its absence in all cases of locomotor ataxia, and its production in favorable cases on suspending the subject from the floor and observing the adduction of the thigh on tapping the patellar tendon, or, as in one case observed, tapping the tendo Achillis.

The crossed knee-jerk is also found to be reinforcible. Reinforcement induces the movement in some cases in which it is not otherwise evident. A case was related in which a very slight tap on the patellar tendon caused violent contractions of both legs, so that the knees are brought together or cross over; a larger tap will cause, in addition, crossing of both arms in a sort of lock-spasm, requiring aid afterward in stretching out the limbs.

The reflex arc involved in movements of this kind is held to embrace the cerebrum.

DR. H. R. STEDMAN, of Boston, asked if this condition was not somewhat similar to the so-called allocheiria?

DR. WALTON had found not only the classic reflex, described recently by Remak, of toe-flexion on stroking the inside of the thigh, but had seen in cases of broken back both dorsal and plantar flexion of the toes on stroking various areas in the extremities.

DR. MORTON spoke of the application of faradism to the right sciatic nerve as having produced a reaction in the muscles of the left shoulder.

DR. GEORGE W. JACOBY referred to a paper read by him a few years ago, in which he had called attention to the phenomenon of irradiation of the electric current.

DR. MILLS believed that the best explanation would be forthcoming from a careful study of the distribution of cells and fibers in the cord and their relation to other parts of the system.

The PRESIDENT considered the title of the paper an unfortunate one, and did not look upon this phenomenon as a crossed knee-jerk at all, but as a contra-lateral muscular contraction. He thought its reflex character was quite doubtful, and that there was no difficulty in accounting for irradiation on anatomic grounds.

DR. DERCUM, of Philadelphia, exhibited a skull illustrating the ancient method of trephining.

DR. KNAPP, of Boston, read a paper entitled "Recurrent Oculo-motor Paralysis." He detailed the case of a man forty-one years old with some nervous heredity, who a year before coming under observation had had severe neuralgic pain over the left eye, with ptosis, external strabismus and numbness of the face, lasting for seven weeks. One year later he had intense pain in the left side of the head, with nausea and vomiting. There was complete paralysis of the left third nerve, with anesthesia of the nose and cheek on the left side, and paresthesia of the forehead. Photophobia was also present. The anesthetic region was extremely tender on pressure, and there was increased discharge from the left nostril. After two weeks the paralysis began to diminish, and after four weeks it had almost wholly disappeared, but the sensory symptoms still continued in a lesser degree. Statistics were given of forty cases, and of ten other cases of a doubtful nature. In only six cases has there been complete recovery from the paralysis in the interval between the attacks, and in four more the pupil remained dilated. In seven cases there was at first com-

plete recovery, but in the later intervals there was some paresis. The division of the cases into periodic and periodically exacerbating hardly seemed warranted, and although some of the cases resemble migraine the affection in most cases is not at all like migraine. Three autopsies have shown lesions involving the nerve, and most cases are probably due to such lesions.

DR. MILLS related that he had observed several cases of recurrent ocular palsy, with involvement of the fifth nerve. He had also seen cases of recurrent facial paralysis. The only probable explanation in most cases is that of organic lesion. He thought Knapp's cases were probably due to a lesion of root-fibers.

DR. MORTON PRINCE agreed with Dr. Knapp in believing that these cases were caused by organic lesion. He believed that pain, as a localizing symptom, possessed very little value. He would rather depend upon motor and sensory paralysis.

DR. WALTON thought that all cases should not be classed together. While many were of nuclear or basal origin, possibly some of the less grave cases were due to recurring edema or possibly vascular disturbance at the cortex, which would probably explain the coincidence of motor and sensory disturbance. Possibly some cases were allied to the severer form of hysteria.

DR. KNAPP, in closing the discussion, said that there was no case of complete recovery on record in which there had been both motor and sensory involvement. In cases of syphilitic origin, in which only one or two branches were involved, the lesion was more likely to affect the nerve after it had left the pons.

DR. CHARLES K. MILLS, and DR. JOHN ZIMMER, of Philadelphia, presented a paper entitled "Circumscribed Softening of the Pons, the Internal Capsule, the Caudatum, and the Lenticula in the same Case." This case presented two limited lesions of unusual interest—one in the pons, and a second involving the internal capsule, a small segment of the caudatum and the lenticula. The pontile lesion was accurately located a week before the death of the patient. The patient, a woman, forty-two years old, had a previous history of alcoholism and of acute articular rheumatism. A presystolic mitral and a systolic aortic murmur could be heard. For eight weeks previous to her admission she had had almost constant headache, worse at night; and on the day before was attacked, without loss of consciousness, with vertigo, double vision, and paresis of the right arm and leg. There was slight impairment of mental action, marked somnolency and imperfect articulation. At rest, the right eye turned strongly to the right, while the left was not deviated. Both eyes could not be turned together to the left. The lateral movement of the left eye to the right was also impaired, and slight nystagmus of both eyes was present. The lids of the left eye could not be brought fully together. Right facial paresis was present, but the tongue was not deflected from the median line. The tendon and muscle phenomena were much exaggerated in the paretic limbs. Anesthesia could not be discovered in any portion of the body. For a few days the patient improved considerably. The loss of power in the leg largely disappeared, and paresis of the face-muscles was only noticeable on smiling, but the woman remained totally unable to turn the eyes to the left beyond the median line. She slept or seemed to sleep much during this time. Her temperature fluctuated slightly below normal.

About eleven days after admission she had a second apoplectiform attack. She was now totally unable to articulate, but understood what was said. She was also unable to expectorate, and there was interference with swallowing. She fell into a stuporous condition, with eyes fixed in the mid-position; the conjunctival and other reflexes were obtunded; the right pupil was smaller than the left; the face was drawn to the right, and the contents of the bladder and bowel were evacuated involuntarily. The woman died between four and five days after this second attack.

The autopsy revealed circumscribed softening with hemorrhagic infiltration. The lesion reached to within 1.5 mm. of the ventral surface of the pons; laterally extending to the raphé, and about the middle of the pons slightly across the mesial line. The area of softening became smaller and more deeply situated as it approached the post-oblongata, which it almost, but not quite, reached. A trans-section through the horizontal furrow, separating the pons and post-oblongata, showed perfectly normal structure.

The second lesion was revealed by a vertical trans-section of the right basal ganglia and capsule. The widest portion of the lesion corresponded to the plane of the cephalic extremity of the thalamus. It was about 17 mm. in its antero-posterior extent. The heart presented valvular lesions, and the kidneys, spleen and lungs pathologic conditions.

The pontile lesions in this case were of unusual interest in the study of the nuclei and root-fibers of the facial, abducens (external oculo-motor), and third nerves (common oculo-motor); and particularly with regard to connections of the facial and abducens. The lesion probably involved the root-fibers of the abducens, the fibers connecting it with the facial fibers or nucleus. The position of the nucleus was such as not by any possibility to involve the cell-nests of these nerves. The lesion involved the crustal portion of the pons, including a portion of the pyramidal tracts and the deep transverse fibers. The lemniscus, central tegmental tract and the structures of the tegmentum in general, probably escaped. The case was also of interest with reference to the question of the partial decussation of the facial root-fibers.

The lesion of the internal capsule was localized about the genu, probably involving the geniculate and speech tracts; the former, as is well known, including the cortico-bulbar bundles for the inferior facial, motor trigeminal and hypoglossal nuclei.

DR. WHARTON SINKLER, of Philadelphia, read a paper entitled "Lesion of Thalamus; Death from Intestinal Hemorrhage." He reported the case of a man, 67 years old, who had worked for many years in a stone-quarry, and had received frequent slight injuries to the scalp, in consequence of being struck by fragments of stone. On one occasion, after having been exposed to the sun, he was suddenly taken ill, and had to be removed to his home in an unconscious condition, where he was seized with convulsions, which lasted for the greater part of two days. After a month he was able to resume his work; but two weeks later he began to have epileptiform convulsions, which recurred at irregular intervals of from one to two a week. The seizures were always preceded

by an olfactory aura, the patient observing the smell of burning sulphur. After a few months the man had maniacal attacks after his fits.

The attacks of epilepsy were of the precursive form. In them the man imagined he was pursued by devils, and would run violently. After one attack the temperature rose, without any discoverable physical cause. The intellectual powers failed; and the man gradually fell into a somnolent condition, which lasted for nearly three weeks, at the end of which time he was suddenly, without premonitory sign, seized with intestinal hemorrhage of a profuse character, and from which he died in about twelve hours.

At the autopsy, the mucous membrane of the colon was found to be softened and deeply injected, but no lesion was found in the way of an ulceration or rupture of a vessel which would account for the hemorrhage.

The brain showed marked evidence of an old leptomeningitis over the left hemisphere, and there was atheroma of the vessels of the base. In the posterior right thalamus there was found a small area of softening. It was about one-third of an inch in length by one-fourth of an inch in its transverse diameter. No other coarse lesion could be found in the brain.

DR. C. L. DANA, of New York, presented a paper entitled "Cerebral Hemorrhage, its Cause and Premonitory Symptoms, together with a Report of One Hundred Consecutive Cases of Apoplexy, with Hemiplegia, and Seventy-nine Cases of Apoplexy, with Autopsy."

Of one hundred non-fatal cases thirty-six were due to syphilis. The special characteristics due to syphilis are that the cases occur in early life; that the lesions are often multiple in character; and that the pathologic condition underlying them is usually thrombosis and softening.

So far as Dr. Dana's experience and records went, cerebral hemorrhages are rarely repeated, and it seems as if in many cases the rupture of an artery changed the vital conditions, as it certainly does the personal habits, so that the attack exercises a conservative influence upon the individual, and actually tends to prolong life.

DR. E. D. FISHER, of New York, read a report of 77 cases; 51 had one attack; 16 two attacks; 9 had three and 1 had six attacks. All are still living. The average age at which the first attack occurred was $44\frac{6}{11}$ years. The longest duration since the attack was twenty-two years.

DR. WILLIAM BROWNING, of Brooklyn, read a paper entitled "Lumbar Puncture for the Removal of Cerebro-Spinal Fluid." He reviewed the main points in this recently devised operation. Brief notes of a few cases were given, as well as directions for its performance. The following conclusions were reached: 1. The method is simple, easily practised and rather attractive. 2. In itself it is usually without danger. 3. By it we certainly can draw off cerebro-spinal fluid. 4. The quantity removed at short sittings has been from one to one and one-half ounces in adults. 5. This, without doubt, represents the amount of free fluid usually present in the lower vertebral canal even when occluded above. 6. In internal hydrocephalus the relief, if any, is but very temporary. In the common form due to tuberculous meningitis the result is not worth the trouble, while in the closed or sacculated forms it must rather do harm than good. 7. As a diagnostic means, *e.g.*, in suspected meningeal hemorrhage, it is valuable. As an index of pressure it may also be worth noting. 8. It is worth further trial: (*a*) As a passing relief in brain-tumors not complicated by hydrocephalus; (*b*) as a substitute for trephining in progressive dementia; (*c*) in certain spinal troubles; (*d*) and possibly as a means of applying medication directly to the spinal meninges. 9. In conclusion it may be said that while admissible in all cases of brain-pressure, there is as yet no established indication for this procedure except for diagnostic purposes.

DR. MILLS said that all operations of this kind were unphilosophic and would accomplish nothing, as the fluid reaccumulates. The same may be said of hydrocephalus. Some good may be done when the fluid is either blood or pus, otherwise the operation is not indicated.

DR. DANA had utilized this method in three cases of alcoholic meningitis (in the so-called "wet brain"). Two recovered and one died. In the adult the operation is difficult. He agreed with Dr. Mills as to its indications and utility. He believed that the operation possessed at least some rational foundation.

DR. THEODORE DILLER, of Pittsburg, read a paper entitled "Non-Operative Treatment of Brain-Tumors." He took the ground that not all brain-tumors which could be localized should be operated on. He cautioned against regarding as successful those operations that merely succeeded surgically. The obstacles in the way of a complete success are many, and the results are disappointing in spite of the rich and growing knowledge of localization. Operations should not be undertaken unless the patient was getting worse in spite of medical treatment.

DR. STARR spoke of the case of a man with a doubtful history of syphilis and all the symptoms of cerebral tumor. Mercury was used and potassium iodid was given in doses of 300 grains daily. There was a marked improvement in all symptoms, and it seemed to be a case cured without operation. The patient died suddenly, and at the autopsy a cysto-sarcoma was found without any evidence of gummatous infiltration.

DR. PUTNAM believed we should only operate when there were definite indications.

DR. SINKLER mentioned the case of a man with Jacksonian epilepsy and no history of syphilis. Two years later symptoms of tumor were present. Mercury and iodid were used, but the man became progressively worse. An operation was performed, but no tumor could be discovered. The wound healed well. Since then the patient has improved steadily in all symptoms.

DR. JACOBY said there was a class of cases presenting all of the symptoms of tumor which get well without operation. He cited the case of a man with many of the symptoms, excepting optic neuritis, in which he was unwilling to make a positive diagnosis. The plasmodium malariæ was found in his blood, and he made a complete recovery under large doses of quinin.

DR. SACHS stated that the results after operation are often disappointing, it may be on account of the delay in operating. He related an instance similar to that of Dr. Starr. At the autopsy there was found a typical glioma. The symptoms had entirely disappeared for several months. In another case with symptoms of tumor, iodid had been used, but the symptoms subsided after thorough mercurial inunction.

Dr. W. M. Leszynsky, of New York, presented an electrode which had been specially constructed with a view to its usefulness in diagnosis.

Third Day—June 1st.

Dr. Henry R. Stedman, of Boston, read a paper on "The Treatment of Convalescence and the After-care of the Insane." He pointed out that the proper conduct of convalescence is vital to mental health. Instances of abrupt recovery with almost no convalescent stage are rare. Although such an event may happen in chronic cases, it occurs, as a rule, in those of short duration—notably confusional insanity and the toxic and neurotic insanities. Lucid intervals or spurious convalescences differ often in no respect from genuine recovery, with the single and essential exception that the sleep does not improve, or becomes worse. This is a valuable indication in the prognosis of permanent return to reason. To the cardinal signs of convalescence should often be added the disappearance of decided fear of a return of the attack and dread of the stigma to follow. It is important to be informed regarding normal and usual physical troubles of the patient, as their reappearance is another and valuable indication of recovery; so, also, a knowledge of the sequence of immediate prodromata of an attack. They are often repeated in reverse order while the patient is getting well. Complete mental rest during menstrual epochs is to be recommended, and application of the mind, even to a slight degree, in study or other work, is equally to be deprecated. Early discharge from the hospital, or from special care away from home, is, as a rule, to be advised against, especially in cases of melancholia with a history of suicidal attempts and after acute mania, the most exhausting form of insanity, and one that leaves the patient particularly susceptible to slight influences for long time.

On the other hand, early removal should frequently be advised in other cases convalescing from melancholia, particularly when homesickness is a marked feature, and occasionally when there is refusal of food. Certain cases of mild mania, also paranoiacs who are independent in the hospital and actively oppose treatment, are steadied by outside life. A change also works well until its novelty has worn off. The first year or so after recovery is a very critical time.

The statements made applied chiefly to well-to-do patients. There is practically no provision outside of hospitals for the after-care of the pauper insane, and practically little advice or other help is given those unfortunates on leaving.

These facts and others have led to the formation in France of protective societies, called *Societies of Patronage*, under official auspices. Their duties are to aid convalescent or recovered pauper patients by gifts of money, clothing, and tools, redemption of articles in pawn, payment of rent, admission to convalescent-homes in cottages intermediate between confinement and complete freedom, or in hospitals or houses of refuge; securing situations for them, and, finally, their supervision wherever employed. This work continues during the first month or two after the patient's discharge. Similar societies or means of relief have been formed in England and Scotland. There could be no better work on the score of both humanity and public economy than the adoption in this country of similar means for the prevention of insanity.

Dr. E. D. Fisher expressed the opinion that patients left the hospital too early. In cases in which they are over-sensitive regarding their previous incarceration, something must be done to care for them and obviate a relapse. He was in favor of establishing convalescent-homes for such patients, and spoke at length in confirmation of the views expressed in the paper.

Dr. Dercum stated that when the element of exhaustion was a prominent causative factor, the patient required detention and care much longer.

Dr. Starr was glad to know that Dr. Stedman favored the earlier removal from asylums of melancholics. One of the chief difficulties was in controlling the family, who did not know how to manage the patient after his return.

Dr. Dana said that the subject was of great economic as well as medical importance, and suggested that a committee be appointed to investigate the matter.

The suggestion was then presented in the form of a motion, which was carried.

The President appointed as a committee Drs. Stedman, Dana, and Dercum.

Dr. Burt G. Wilder, of Ithaca, exhibited a suicide's brain with two pistol-ball wounds, together with a dozen photographs of various aspects, and blackboard diagrams of the left side and of a trans-section at the level of the fatal wound.

A dentist, thirty-five years old, was found in his office dead, with a 22-caliber revolver clasped in his right hand. There were two bullet-holes; one in the middle of the forehead, the other in the right temple, neither ball having emerged.

The first ball, presumably deflected by the skull, passed caudo-ventrad to the cranial floor and was reflected dorso-caudad at nearly the same angle to a point just cephalad of the precommissure, where it lodged, having merely abraded the mesial surface of the left frontal lobe. The second ball entered at the right subfrontal gyre, passed obliquely sinistro-caudo-dorsad, tore the callosum and intervening structures and emerged in the second left central fissure. As there was no suspicion of foul play, and documents in the handwriting of the deceased declared his intention to commit suicide, the case exemplifies the possibility of two self-inflicted bullet-wounds of one brain. The fissures present many peculiarities. The most perplexing is the apparent coexistence of two central fissures on each side. Only two such cases have hitherto been recorded, by Giacomini and Calori. Suicide had been committed by a grandfather and one uncle, and attempted by another uncle.

Dr. Dana said that he had no doubt that the anterior of the two fissures was the fissure of Rolando. The interruption of this fissure on one side by a bridging convolution was extremely rare and very interesting. The brain presented a unique fissuration. Dr. Dana could not understand how a primary fissure like the Rolandic could be doubled in any event, and was skeptical of the genuineness of reported cases.

Dr. Edw. B. Angell, of Rochester, read a paper entitled "Case of Infantile Hemiplegia, Imbecility, and Epilepsy; Craniotomy; Marked Improvement." The salient features of the case were a severe forceps-delivery,

succeeded by double ptosis, occasional tonic spasm of the right arm, contracture and hemi-palsy of the right hand. Physical and mental development was slow, and epilepsy, with from three to five seizures daily, supervened three months prior to the operation. At the time of examination the child was partly imbecile. The skull-measurement gave a cranial index of 0.77; the palate was high-arched, the teeth jagged, and the right wrist and hand, much smaller than the left, were helpless. A diagnosis of pressure in the neighborhood of the hand-center of the left motor area, due either to a hemorrhagic plaque or cyst, was made. Craniotomy was decided upon as a tentative measure, with a view of relieving pressure and consequent symptoms, while avoiding the greater risk of opening the dura necessary to a removal of the cyst-wall. Upon removal of the trephine-button a subdural hemorrhagic cyst was found. The cranium overlying the cyst had become much thinned, and was freely cut away beyond the limits of the cyst. By an aspirating needle a half-dram of fluid was removed; otherwise the dura was not injured. The scalp-incision healed readily, but through an over-tight bandage edema developed, which by the eighth day caused sufficient pressure to develop a severe convulsion and high temperature. With the remedying of this condition marked improvement in all the symptoms ensued.

Three months after the operation there had been no recurrence of the epileptic attacks, while there was a commensurate improvement in the mental and moral condition.

DR. MILLS considered it presumable that the cyst which was not opened was a porencephalic cavity, and that opening and draining it would have been useless.

DR. PUTNAM agreed with Dr. Mills. He said it was rarely possible to remove a cyst satisfactorily. In a case seen by him the cyst was tapped and the drain left in. Improvement followed.

DR. W. A. HAMMOND spoke of two cases in which craniotomy was performed. One was eighteen years of age, and became an imbecile as a result of an injury to the head. He remained in this condition four years. After operation there was improvement at the end of two months. At the end of a year the improvement was marked. In the other case of a similar character the operation was followed by improvement.

THE PRESIDENT said that cysts differed in character. The superficial cysts were due to meningeal hemorrhage during labor, and could be satisfactorily treated by operation.

DR. ANGELL, in closing the discussion, said this was not a case of porencephalus, but an arachnoid cyst from a meningeal hemorrhage.

DR. CHAS. HENRY BROWN, of New York, read a paper entitled "Infantile Amyotrophic Lateral Sclerosis of the Family Type." He reported the case of a boy, fifteen years old, who presented marked emaciation, particularly in the upper part of the body, and paralysis and atrophy of all the facial muscles, excepting those of mastication. Fibrillary twitchings were present all over the body. The superficial and deep reflexes were active. Ankle-clonus was demonstrable. There was double lateral curvature of the spine. Mentally the boy was fairly bright. He cried readily and was amused at trifles. He was microcephalic, and acted and appeared like a child of ten. There were evidences of a general arrest of development. The case is considered as belonging to one of the family types of infantile progressive bulbar paralysis, plus the same implication that is found engrafted upon the progressive poliomyelitis of adults, and which gives us amyotrophic lateral sclerosis. In muscular myopathies the respiration is not involved; the upper facial muscles are usually unaffected; and the "tapir mouth" is not observed. The atrophy is more irregular, more nearly bilateral: that is, it is worse on one side. The electric reactions are not of especial importance in diagnosis. In some reported cases of infantile progressive bulbar paralysis they have been normal; in others there has been reaction of degeneration.

To place this case among the scapulo-humeral, or facio-scapulo-humeral types of muscular atrophy is out of the question. Though the neck is much thinned, the scapulo-humeral group and the back muscles are generally the best the patient has. What muscles he does possess are active, and the exaggeration of reflexes, the fibrillary twitchings, and the retractions of tendons, present though slight, preclude a peripheral origin of the disease. As far as is known, no case of the kind has ever been reported and diagnosticated as infantile amyotrophic lateral sclerosis of the family type. In all the cases reported of these bulbar diseases belonging to groups of family types there has been marked difficulty of respiration and special implication of the upper branch of the trifacial nerve.

DR. KNAPP showed a microscopic specimen from a case of amyotrophic lateral sclerosis which occurred in a man fifty years of age. The disease progressed very rapidly. Death took place at the end of fourteen months of broncho-pneumonia. There were no bulbar symptoms. The section presented showed marked vascularity in the sclerosed portions of the cord.

DR. PUTNAM reported an analogous case of bulbar paralysis in a young child.

DR. PRESTON, of Baltimore, had seen the case of a child two years of age in whom spastic symptoms such as exaggerated knee-jerk and ankle-clonus developed soon after an attack of acute poliomyelitis.

DR. F. X. DERCUM and DR. W. W. KEEN, of Philadelphia, presented an article entitled "Two Cases of Ingravescent Cerebral Hemorrhage Treated by Ligation of the Common Carotid Artery." In the first case reported the symptoms pointed to a slowly progressive capsular hemorrhage extending over three days before ligation of the common carotid was resorted to. The symptoms were steadily progressive and threatened a fatal termination. Ligation of the carotid, as proposed by Mr. Horsley, promptly arrested the symptoms, and the man made an excellent recovery. Months afterward merely symptoms of a spastic hemiplegia persisted, but they were not very marked.

In the second case the symptoms pointed to a progressive hemorrhage occupying eight hours. The patient's condition was so grave at the time of the operation that little was hoped from it, and indeed it proved useless, the patient dying several hours afterward.

Dr. Dercum pointed out that the class of cases in which benefit is to be hoped for from ligation of the

common carotid are those in which the hemorrhage is decidedly ingravescent in type. He also dwelt upon the difficulties of a differential diagnosis between hemorrhage and thrombosis in such cases, and pointed out that even in case of an error in diagnosis it could not be said that the operation involved additional risk to the brain.

Finally he suggested that instead of ligation of the vessel the expedient of compression of the common carotid should be tried in every case of apoplexy as soon as the physician arrived. A surgeon is not always at hand, and besides, compression of the carotid is so simple a procedure that a bystander can easily be instructed in its application.

Dr. Frank Fry, of St. Louis, knew of several instances in which the operation had been done. All proved fatal. He believed that the operation was not indicated or justifiable.

Dr. Knapp believed that the neurologist does not see the case until it is too late to make a satisfactory diagnosis.

The President thought the chief difficulty was in diagnosis and that the hemorrhage was usually a self-limited one.

Dr. Dercum, in closing the discussion, said the operation was only indicated when the diagnosis of ingravescent apoplexy was defined.

Dr. W. A. Hammond, of Washington, read a paper on "Merycism." He reported the case of a young man whose mental condition was impaired, and who was also the subject of merycism.

No special treatment was undertaken to correct the merycism, but the patient was trephined for the purpose of improving his mental condition. There were no unusual features connected with the operation, but the regurgitation after meals did not occur till the fifth day, when there was a slight return. Eight days later a button was removed from the corresponding part of the left side of the skull. From that time (about ten months ago) to the present there has been no regurgitation. Whether the cure of merycism in this case was directly due to the operations on the cranium, or was the result of the mental improvement, is a question which it would be difficult to answer.

Dr. Knapp referred to two cases that had come under his notice. Both were in physicians in good mental condition. He thought a distinction should be made between congenital and acquired merycism.

Dr. Lloyd believed that some cases should be considered as a neurosis allied to hysterical vomiting, such as regurgitation from the esophagus.

The President had seen a man who had conquered the habit by the exercise of his own will. His views were in accord with those expressed by Dr. Lloyd.

Dr. Hammond said that acquired merycism was always due to overloading the esophagus and to the bad habit of rapid eating. He thought it extremely doubtful as to its being a neurosis.

Dr. J. Hendrie Lloyd, of Philadelphia, exhibited a large number of sections from the mid-brain, pons, medulla, and spinal cord of a case of chronic chorea.

The following gentlemen were elected to active membership: Dr. Ira Van Gieson, of New York; Dr. E. B. Lane, of Dorchester, Mass.; and Dr. E. D. Bondurant, of Tuskaloosa, Ala.

The following papers were read by title: "Acute Angioneurotic Edema," by Dr. H. M. Bannister, of Kankakee. "Present Hospital Care of the Insane," by Dr. S. B. Lyon, of New York. "The Genesis of Hallucinations, Illusions, and Delusions," by Dr. H. A. Tomlinson, of St. Peter, Minn. "A Case of Acromegaly," by Dr. H. T. Pershing, of Denver. "Significance of Exaggerated Knee-jerk and Ankle-clonus," by Dr. G. M. Hammond, of New York. "Report of a Case of Spinal Syphilis and one of Intra-cranial Syphilis," by Dr. L. C. Gray, of New York. "Remarks on Cortical Sensory Localization," by Dr. Charles K. Mills, of Philadelphia. "Traumatism as a Cause of Locomotor Ataxia," by Dr. Morton Prince, of Boston. "Observations upon an Anencephalic Monster," by Dr. E. B. Angell and Dr. Henry Elsner, of Rochester. "Cerebral Edema," by Dr. George J. Preston, of Baltimore. "Gastro-intestinal Neurasthenia," by Dr. L. Weber, of New York. "A Study of the Temperature-sense," by Dr. W. H. Riley, of Battle Creek. "Aphasia following Acute Infectious Diseases," by Dr. P. C. Knapp, of Boston.

The following officers were elected for the ensuing year: *President*, Dr. Philip Coombs Knapp, of Boston. *Vice-Presidents*, Dr. F. X. Dercum, of Philadelphia, and Dr. W. A. Jones, of Minneapolis. *Secretary and Treasurer*, Dr. G. M. Hammond, of New York.

NEWS ITEMS.

The St. Louis Clinique has passed under the editorial control of Dr. Emory Lanphear.

Correction.—In the 16th line from the bottom of the first column of p. 31 of The News of July 14th, the figures 0.2 should read 0.02.

The Cholera is reported to be spreading with alarming rapidity in St. Petersburg. On July 14th, 218 new cases, with 69 deaths, were reported. During the week ending July 15th there were 875 cases, with 294 deaths. On July 17th, 196 new cases, with 79 deaths, were reported. It is announced that cholera prevails in Dantzic, in Prussia. It is also reported that cholera is spreading throughout the Chinese Empire, and that the government officials are suppressing the facts.

Joseph Hyrtl, the distinguished anatomist, died at Vienna, on July 17th, at the age of 83 years. He was Professor of Anatomy in the University of Prague from 1837 to 1845, when he was elected to a similar chair in the University of Vienna. He was the author of a "Manual of Physiological and Practical Anatomy," and a "Manual of Topographical Anatomy and its Applications."

The American Journal of Insanity has been sold and transferred to the American Medico-Psychological Association, of which society it will henceforth be the accredited organ.

The journal will be edited *ad interim* by a publication committee consisting of Dr. Edward Cowles, President, and Dr. Henry M. Hurd, Secretary of the Association, and Dr. Richard Dewey, with the last named in immediate editorial charge. The office of publication has been transferred to Chicago.

ORIGINAL ARTICLES.

ON LEAD-PALSY IN CHILDREN; WITH A REPORT OF THREE CASES.[1]

BY WHARTON SINKLER, M.D.,
OF PHILADELPHIA;
PHYSICIAN TO THE ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES, AND NEUROLOGIST TO THE PHILADELPHIA HOSPITAL.

A CAREFUL search through current literature and the text-books shows great paucity of material in regard to plumbism in young children. In an admirable and thorough article on lead-poisoning, James J. Putnam[2] remarks that the justification for his article "is found not in the abundance but in the meagerness of the present accumulation of facts relating to children, and the importance of taking steps toward increasing it." I have been able to find no other cases besides those which Dr. Putnam has quoted in the complete table which he has added to his paper.

Wilson, in *Pepper's System of Medicine*,[3] says: "Lead-poisoning is an affection of adult life. Of 102 cases, two only occurred in individuals below twenty years of age."

D. D. Stewart, of Philadelphia, whose article on poisoning by buns colored with chrome-yellow attracted so much attention a few years ago, writes me that he made a thorough search through the literature of lead-poisoning when investigating these cases, and made notes of all nervous cases, especially those with brain-symptoms. He found many cases of cerebral disorders, like convulsions, which occurred in children, but none of paralysis. He also remarks that in German literature there are a number of accounts of whole families being poisoned by lead, through working and living in the potteries; but there are no records of palsies in children among these cases, though paralyses in the adults are common; and it was related that the children had headache and convulsions.

Among Stewart's cases of chronic lead-poisoning from eating the chrome-yellow buns, seventy-nine in number, there were many children. These were especially affected with convulsions, but there were no cases of wrist-drop or other palsies among them.

There is apparently no reason why children should not be as susceptible to lead poisoning as adults. Children are as much exposed to the dangers of lead-poisoning, except in those cases which occur among workers in lead—as, for instance, painters, manufacturers of white lead, and those employed in potteries.

There are many cases on record in which children of various ages have been seriously poisoned by the absorption of lead into the system. On the other hand, in epidemics of lead-poisoning from drinking-water, the proportion of cases in children is small. In the epidemic which occurred at Tredegar, England, reported by Dr. Brown, and quoted by Putnam, there were no serious symptoms in any person under eighteen years of age among fifty-two cases of well-marked lead-poisoning.

Putnam refers to another epidemic, in which thirty-eight persons were exposed to poisoning through drinking-water. Thirteen were affected; but no children were attacked, although there were eight among those who had been drinking the infected water. It is probable, therefore, that children are not so liable to lead-poisoning as adults; and this is no doubt due to the fact of their possessing more active powers of elimination; their greater bodily activity, and the greater energy of all of their secretions, causing the ready elimination of the lead from the system.

The sources of lead-poisoning are so numerous that it is remarkable that more cases do not occur. Drinking-water in cities, from passing through lead pipes, frequently becomes charged with lead. Lead is to be found in cooking utensils, in red rubber, which is sometimes used for making nipples for nursing-bottles, in the solder used in cans, coverings of sweetmeats, and in lead chromate, which is used in coloring toys, cloths, and other articles.

It is evident from the cases that have been recorded, in which a large number of persons have been equally exposed to the danger of lead-poisoning, that the degree of susceptibility varies, as but a small proportion of the persons exposed are attacked.

The symptoms of lead-poisoning in children which have been most frequently noted are disturbances of digestion, such as colic and vomiting; and the cerebral symptoms, indicated by headache, convulsions, and stupor. Chronic lead-poisoning is most likely to be manifested by a general loss of flesh,

[1] Read before the Association of American Physicians at Washington, D. C., May 31, 1894.

[2] Encyclopedia of the Diseases of Children, vol. iv, p. 615.

[3] "Chronic Lead-poisoning," System of Medicine, vol. v, p. 686

failure of appetite, and the earthen hue of the skin, with a jaundiced condition of the conjunctiva. In chronic lead-poisoning disorders of digestion are most common; constipation, attacks of colic and vomiting frequently occur, and there is other evidence of derangement of the stomach in the defective assimilation that exists. In other cases symptoms of kidney-disease are present; and it is well known that there is a form of nephritis due to accumulation of lead in the kidneys.

The symptoms dependent upon disease of the nervous system due to lead-poisoning are motor and sensory. The most common of these, of course, is paralysis of the extensor muscles of the forearms. In children, however, it is a noteworthy fact that the paralysis is as liable to affect the lower extremities as the upper. There are but few cases reported in which sensory disturbances have been met with in children. Cerebral symptoms are not uncommon in children. The lead encephalopathies in children have been frequently met with, especially, as already remarked, among the cases reported by Stewart, and Putnam refers to other cases.

The cases of lead-palsy in children which are quoted by Putnam are, first, that of a girl of eight years, reported in the *Lancet*, who suffered from paralysis of all four extremities, from the use of Sheffield drinking-water; and a similar case which was related by Seligmüller, who credits it to Duchenne.

H. D. Chapin[1] gives the history of two cases of lead-palsy in children. I will detail these at some length because of their curious similarity to the cases which I shall report later.

The father was a painter, and kept paint in the house, so that the children were constantly exposed to its influence. They enjoyed good health until December 25, 1882, when the room in which the children lived was painted. On January 1, 1883, one week later, F. W., aged seven years, was seized with abdominal cramps; on the next day R. W., aged five, complained of the same symptoms. The pain lasted for four weeks, and there was intense thirst. There was then pain and soreness in the legs, and the children were averse to walking. By the last of January they could not stand. They then improved somewhat, but during February another similar attack occurred. There was pain, followed by paralysis, and the loss of power lasted much longer than in the first attack. On May 3d, a third attack occurred in one boy, in which the hand was affected. The children now came under Dr. Chapin's care. They could walk with difficulty, and a blue line was observed upon the gums. They were lost sight of for a year, when they were examined again by Dr. Chapin. They were then worse than they had been before; they were utterly unable to walk, and pains throughout the body were complained of. The teeth were loose, the gums were spongy, and there was headache. The muscles did not respond to faradism or galvanism, but sensation was normal. The house in which they lived had been cleared of paint a year previous, and there was nothing to account for the repeated attacks.

The children were admitted to the hospital, and after treatment they improved greatly and were able to walk somewhat. An examination of the urine showed the presence of lead. There was partial paralysis of the anterior leg-muscles, and these showed the reaction of degeneration.

Dr. Chapin called attention to the striking resemblance of these cases to spinal paralysis of infancy. This writer also related the case of a child, two and a half years of age, in which a solution of lead acetate was applied to a splinter-wound. In four days both legs were paralyzed, but the child soon got quite well. This is, I think, rather a doubtful case of lead-paralysis.

The sixth case is reported by Putnam, from the records of the Children's Hospital, Boston, in which a girl of six years, after having been exposed to a freshly-painted house, had attacks of vomiting, which affected her at intervals for two weeks, followed by weakness of the legs, toe-drop, and waddling gait. A month later there was weakness of the fingers and the wrist; the extensor muscles were affected in both arms and legs, and the knee-jerks were absent. Two months later the paralysis had disappeared, but the legs were easily fatigued.

A seventh case has been reported by Miller,[1] in which a child of four years was poisoned by drinking-water; but it is merely observed that there was a paralytic state.

A case is reported by Letheby, in which a child of six years took lead acetate in doses of one-fifteenth of a grain two or three times a day for nine weeks. There was loss of flesh, colic, paralysis of the limbs, convulsions and coma, followed by death, which occurred two days after withdrawal of the medicine.

These constitute all the cases of lead-palsy in children that I have been able to find, except one reported by Suckling,[2] in a boy of fourteen years, who worked in zinc and lead for eighteen months, and who presented evidences of multiple neuritis, without other symptoms of lead-poisoning.

The following three cases came under my observation at the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases. The parents were healthy and had nine children. One child died of spinal meningitis at five years of age. It had from birth a large head. Another child died of

[1] New Orleans Medical and Surgical Journal, 1873, vol. i, p. 198.

[2] British Medical Journal, 1888, vol. i, p. 649.

convulsions at three years of age. Four other children are perfectly healthy, and the remaining three are the cases of which I shall relate the histories.

The father is a house-painter by occupation, and had his shop in the house in which he lived. The children frequently played about the room in which he kept his paints, and often got the paint on their hands and faces, and sometimes were seen to put it in their mouths.

CASE I.—Sarah McD., aged ten years and six months.

Previous history. Her health had always been good previous to the onset of the present trouble. She cut her teeth and walked at an early age, and never had any intestinal disorders.

She was brought for treatment to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, in July, 1889. About one month previously, she awoke in the morning with partial loss of power in the legs. She had fever of short duration, and there was constipation and some vomiting, but no colic. The weakness of the legs steadily increased, and pain in the legs was complained of. Four weeks later the arms became weak, and there was gradual wasting of all the limbs. The weakness and atrophy were most marked on the right side.

The child was treated as an out-patient by means of electricity, and in October, 1889, she had almost completely recovered the use of her legs. In June, 1890, she grew gradually weak for about a week. She then lost the power of standing, and could not use her arms. In this attack there was fever, vomiting, and constipation, but no colic. There were no convulsions, no coma, and no headache. On July 14, 1890, she was admitted to the hospital. Her condition was then as follows:

There was loss of power in all of the muscles of the legs, more or less complete; and there was complete wrist-drop and ankle-drop. The patient was unable to use the hands or arms, except that she could slightly move the arms at the shoulders. There was great muscular wasting, but no changes in sensibility. The patient's mind was clear, and her general health was good.

The electric examination showed absence of response to the faradic current in the extensors of the legs, thighs, and forearms, and diminished reaction in the flexors to galvanism.

The reactions to the galvanic current were as follows:

Right tibialis anticus and common extensors	R D
Right peronei	K cl > A cl.
Left tibialis anticus and common extensors .	K cl = A cl.
Left peronei	K cl > A cl.
Left forearm-extensors	R D
Right forearm-extensors	K cl > A cl.

The patient was treated with daily faradization and massage, and in about four months she was able to walk about and to use the arms freely. She was discharged greatly improved, November 8, 1890.

She was examined on May 17, 1894, and her condition was as follows:

Both feet are flat, and foot-drop is marked on both sides, when sitting. The left great toe is abducted, and all of the toes of the right foot are abducted, the great toe especially. This toe is also rotated to an angle of about 90°, so that its dorsal surface points laterally. The patient is unable to flex the feet. The left leg is a little smaller than the right. There is no wasting in the arms, and the muscular power in both is good. In walking, there is a tendency to walk on the toes, on account of a slight contraction of the tendo Achillis. The patient's general health is good, and the gums are free from discoloration or disease.

The eyes were examined by Dr. A. G. Thomson, who made the following report:

The pupils are equal, and react normally to light; the discs are a trifle red; the outlines of the discs are well marked; there is no lesion of the fundus; the muscular balance is good; the form and color fields are normal. V. = 20/20 with both eyes.

CASE II.—Harry McD., a brother of the preceding patient, was admitted to the hospital July 11, 1892. He was six years of age, was born normally, and was breast-fed. He began to cut teeth at the age of three months. He was healthy until the sixth month, when he had convulsions, which lasted three days. The spasms were general, but there was no subsequent paralysis. When sixteen months old he had entero-colitis. He began to walk at fifteen months of age. This child also had access to the room in which his father's paints were kept, and was frequently besmeared with paint. In November, 1891, he had an attack of fever accompanied by vomiting, loss of appetite, colic, and constipation. This attack lasted for about three weeks, when it was noticed that the legs and arms were weak. The arms could not be raised above the head, and the hands dropped at the wrists. There was loss of power in the legs, so that the child was unable to walk. Complaint of pain in the knees was frequently made. The legs and arms grew steadily thinner, and the muscular weakness increased.

On admission the child was pallid and thin. He possessed normal intelligence; his digestion, appetite, and bowels were in good condition. He was unable to stand, or to walk, and there was but little power in the muscles of the legs. The feet were in a position of ankle-drop, and attempts to flex the feet were futile. The arms could be moved slightly at the shoulders, but the power in the muscles of the arms and forearms was almost absent. There was complete wrist-drop. There was no facial paralysis.

Atrophy. There was marked wasting in the muscles of both arms and legs. There was no response to the faradic current; and there was great quantitative change in the extensors of the thighs, arms and forearms, to galvanism. R. D. was present in the extensors of the left leg, and in the extensors of the right leg. The knee-jerks were absent, and the arm-jerks were decreased.

The patient was treated with massage and electricity, and steady improvement took place; so that in five months he was able to walk about unassisted, but the toes were dragged and the feet

flapped in walking. The patient had gained flesh, and the color was good.

March 27, 1894. The condition of the boy was noted as follows: He walks with the feet far apart and the toes inverted. The left leg is much weaker than the right. The circumference of the right thigh is eight inches, of the left thigh eight and a quarter inches; that of the right calf is six and a quarter inches, of the left seven inches. The knee jerk is absent on both sides, and there is no reinforcement. There is left foot-drop, and the muscles of the leg of this side are markedly wasted. The left hand is weak, and there is atrophy of the thenar and hypothenar muscles. The elbow-jerks can be elicited.

The electric examination shows good response in the peroneal and calf muscles. The flexors of the thighs respond readily. R. D. is found in the tibialis anticus and extensor communis of both legs. The eyes show nothing abnormal.

Case III.—Eddie McD., aged three years, a brother of the two previous patients, was admitted to the hospital July 11, 1892. He had always been healthy up to the present trouble. He began to walk at about the age of two years, but only with assistance. It was then noticed for the first time that the right leg was weak and that the foot was dragged in walking. He complained of some pain in the right knee at the same time. The leg continued to grow smaller until his admission to the hospital.

On admission, it was found that both legs were weak and that there was complete wrist-drop. The extensors of the hands seemed to be the only muscles which were affected, as the arms could be moved in all directions. The electric examination showed reaction of degeneration in the muscles of both legs. The knee-jerks were absent on both sides. This patient also improved under the use of massage and electricity, and in five months he began to walk unassisted, but dragged the toes on both sides, more especially on the right side. The knee-jerks had returned and were slightly exaggerated.

March 27, 1894. The patient looks strong and ruddy. He runs about with freedom, but drags the right foot, and when lying down there is right foot-drop. The leg is wasted and there is inability to flex the foot. The thighs are each ten inches in circumference; the right calf is seven inches, and the left seven and a half inches. Sensation is perfect, and there are no trophic changes. The left hand is somewhat weaker than the right. The right knee-jerk is grossly exaggerated, but there is no ankle-clonus. The knee-jerk on the left is slightly exaggerated. The electric examination shows normal reactions in all of the muscles of the left leg and of the right calf. In the extensors of the right foot there is loss to the faradic current and reaction of degeneration.

In neither of these children was any blue line on the gums observed, or any diseased condition of the teeth or gums. The digestive organs were in fairly good condition on admission to the hospital, and although the children were thin and pallid, there was no distinct saturnine cachexia noticeable.

When the two boys were first admitted, an attempt was made to examine the urine for lead, but this was not successful. They were readmitted in March, 1894, and after potassium iodid had been administered for several days, the urine was collected, evaporated, and carefully tested for lead on three different occasions; but no trace of lead could be recovered. The investigation was made in a careful and thorough manner by Dr. J. E. Talley, the resident physician.

The significance of the presence of lead in the urine in small quantities is not great, when we consider the statement of Putnam, in the article already referred to, that Drs. Comey and Worcester had analyzed for him the urine of more than 150 persons living mainly in the neighborhood of Boston, and not presenting symptoms of lead-poisoning, and found traces of lead in about 25 per cent. of them. Dr. J. Dickson Mann[1] gives as the result of a careful study of two cases these conclusions: "That lead is slowly and more or less continuously eliminated by the bowels, and, *to a very much less extent*, by the kidneys; that when once deposited in the tissues it exists as a stable compound, over which drugs have little, if any power." He also asserts that potassium iodid has absolutely no power as an eliminant of lead, although he admits that it may be beneficial in some other way in cases of chronic lead-poisoning.

In the cases that I have related, the symptoms presented were those of poliomyelitis; indeed, when Sarah McD., the eldest child, first presented herself at the Infirmary, I believed the case was one of that disease; and when she returned a year later with a relapse, I regarded it as a remarkable instance of a second attack of infantile spinal paralysis. It was not until the second child was brought to me for treatment that I suspected some common cause for the disease, and thought that it might be one of those instances of epidemic poliomyelitis due to microbic infection.

On inquiring into the history of the children I found that their father was a painter, but the mother strenuously denied that they had been exposed to contact with the paints. When the third case was brought to me I asked my friend, Dr. J. H. Rhein, to visit the home of the children; and he discovered the fact that there was a great deal of white lead lying about, and that the children had frequently played in the paint room, and were often daubed with paint.

The resemblance of lead-palsy in children to poliomyelitis has been noted by several writers; and it seems possible that some of the cases that have been recorded as instances of poliomyelitis may have been due to chronic lead-poisoning.

[1] British Med. Journ., February 25, 1893.

The pathology of lead-poisoning in children is generally considered as consisting in changes in the peripheral nerves; and these alterations are very closely allied to those met with in the ordinary forms of multiple neuritis. There is good reason to believe, however, that in many cases of typical lead-paralysis the symptoms are due primarily to the direct action of the lead upon the muscles. It is also probable, and this is also suggested by Putnam, that chronic lead-poisoning may produce typical changes in the anterior horns of the spinal cord, and thus give rise to a poliomyelitis, identical in its symptoms with the acute, or, so to speak, idiopathic form of the disease.

SOME PHYSIOLOGIC EFFECTS OF MUSIC IN HYPNOTIZED SUBJECTS.

BY ALDRED S. WARTHIN, PH.D., M.D.,
DEMONSTRATOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF MICHIGAN, ANN ARBOR.

HAVING been led during the past year by an interest in musical esthetics to an investigation of the expressive power of music, especially with reference to the Wagnerian music-dramas, I came upon certain results extremely interesting in their nature, and certainly valuable as contributions to our knowledge of musical effect. These were the result of experiments made to ascertain the physiologic and mental effects of music in subjects that had been put into a state of hypnosis.

It has long been known that music is capable of inducing changes in certain functions of the body, as the circulation, respiration, etc. The marked effects that musical sounds have sometimes produced in animals are also familiar. From the legends of Apollo down to physiologic experiments of modern times, records have been made from time to time of such observations, but the field has, apparently, appeared so little promising that scientific experimentation of any importance has not been done in this line. The majority of the observations recorded have been of a popular nature, in like manner noted, and are, chiefly, of little value. Occasionally these are collected, new facts added from the author's experience, and an attempt made to draw some sort of a conclusion or to arrive at some law of musical effect. Among the more important of these are: "Effets et Influence de la Musique sur la Santé et sur la Maladie" (Chomet). "Sull' importanza fisiologica e terapeutica della Musica" (Vigna). Also occasional articles appear in the medical journals upon the effects of music in disease, especially in abnormal mental conditions. But prolonged and careful investigation seems never to have been made in this direction, and the results of the recorded observations are practically of little importance.

While attending performances of Wagner operas at Munich and Vienna an observation of musical people who were deeply affected by the Wagnerian music led me to the thought that these musical "Schwärmer" in their state of musical *en rapport* were in a condition of self-induced hypnosis, and further observation tended to confirm this idea. In giving themselves up to the emotional effect of the music, these people were putting forward their subjective natures at the expense of their objective relations to the world: for the time, being in a state exactly analogous to the hypnotic state, if not really the same. From this it was but a quick passage to the thought that the power of music, whatever that might be, would be displayed and felt in its greatest and purest force in conditions of complete mental subjectivity, when all external connections and relations have been removed—a state in which nothing but the music would exist for the mind—that is, a complete hypnotic state.

At the first opportunity for making such experiments, the effect of music upon persons who had been put into the hypnotic state was tried with results of a very interesting and remarkable nature. After a great deal of research I have not been able to find elsewhere anything of the nature of these experiments, or to find anywhere records of such decided effects of music upon the physiologic functions of the body. These effects were so constant and so marked in all of the cases experimented upon that I consider them worthy of report.

The number of cases experimented upon is only seven, the small number being due to the reluctance of the average normal individual to be made the subject of hypnotic experiments; but these seven represented a wide range of individual character within limits apparently normal. Of this number, five were men, two were women. All were healthy and passed for normal individuals, and as possessing more than an average mental ability. No nervous or abnormal condition existed in any subject, and only one could be called emotional. Four were physicians and teachers, the others students. No one of them had either been hypnotized before or had been especially interested in the subject. All but one consented to the experiments with reluctance, and entered into the hypnotic state only because of the scientific aim. No one of the subjects was a musician in any practical way, and with but one exception they did not possess any marked development of the musical sense. In the normal state music produced no great emotional effect and no apparent physiologic action. All but one were more or less fond of musical sounds, and derived pleasure from the art.

As all experimental work in hypnotism is especially liable to error through deception, either voluntary or involuntary, on the part of the subjects,

especial care was taken to avoid this, although the character of the subjects was such as to make this precaution seemingly unnecessary. The experiments were made at different times, and no occasion was given for the imitation of results obtained in one subject by any of the others. Moreover, as the chief effects were physiologic, there was no chance for any such deception.

The subjects were hypnotized by the common method of fixing the eyes, passing the hands over the head and face, and at the same time making word-suggestion. After several trials they could usually be brought into a deep hypnotic state. This was done in a room containing a piano, the subject being placed in a chair or upon a lounge near the instrument. As soon as the hypnotic state was induced the following suggestion was given to the patient: "You are dead to everything else in the world except the music which is now to be played, and you will feel and know nothing but this music. Moreover, when awakened, you will remember what effect it has had upon you." A composition would then be played, and the physiologic effects noted; and then the subject was awakened and asked to give his experience, and it is the result of some of these experiments that I now wish to give.

Mr. M. is a physician, forty years old, fond of music and of rather emotional nature. He is easily hypnotized and passes quickly into the deepest hypnotic state. Wagner's "Ride of the Walküre" was played from the piano-score. The subject's pulse became at once more rapid, fuller, and of increased tension. As the music continued the pulse-rate rose from 60, his normal rate, to 120 per minute, becoming very quick, full, and of low tension; at the same time the rate of respiration was increased from 18 to 30 per minute. The subject's face showed great mental excitement; his whole body was thrown into motion; the legs were drawn up and the arms tossed in the air; at the same time the whole body was bathed in a profuse sweat. On being awakened the subject said that he did not perceive the music as sound but as *feeling*, and that this feeling was a sensation of wild excitement, brought on by "riding furiously through the air." This state of mind brought up before him in the most realistic and vivid manner imaginable the picture of the ride of Tam O'Shanter, which he had seen years before; that almost immediately this became real to him, and in some way he took part in the wild chase, not as a witch, devil, or as Tam, but in some way his consciousness was spread through every part of the scene, being of it, and yet also playing the part of a spectator.

Mr. O. is twenty-two years old, of average musical and emotional development. He is not so easily hypnotized as the first subject and does not pass into such a deep state. Under the influence of the same musical composition, the same effect upon pulse and respiration was produced, the former rising in rate from 70 to 120 beats per minute. The patient's expression remained unchanged, and no movement of the body was made. The skin was covered with profuse perspiration. When aroused the subject said that he had received a perfect sensation of "riding furiously through the air," and that this feeling had created for him a perfect picture of a horse-race in the most complete and startling detail.

The effect of this composition upon all was practically the same. All experienced a "feeling of riding," which almost immediately brought up from their past experience some association directly connected with this state of feeling; as, for instance, the physician had at one time been deeply impressed by a large picture of Tam O'Shanter's ride; the student had previously attended horse-races with great interest. Only one of the subjects knew of the connection of the music with the story of the "Walküre;" and to that one it always expressed and pictured the wild ride of the daughters of Wotan, the subject taking part in the ride.

It is here to be noted that the subjects could not tell afterward what music had been played to them while in the hypnotic state; and that the same composition played to them while in the normal state produced no impression comparable with that received in the hypnotic condition, and was without physiologic effect.

Appended are some pulse-tracings, taken from one of the subjects during the playing of the "Ride of the Walküre." Though made with a very poor instrument, they were taken under exactly similar conditions, and in the same period of time, and thus show the relative changes in the pulse-wave under the effects of music.

Tracing 1.

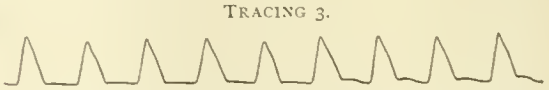
Pulse-tracing in normal condition; 70 beats per minute.

Tracing 2.

Pulse-tracing from same subject in hypnotic state; 82 per minute.

In all of the subjects, after being hypnotized, there was a slight increase in the rate, with a decrease in size and tension.

Tracing 3.



Pulse-tracing from same subject, in hypnotic condition, just after the playing of the selection from Wagner's "Die Walküre" had been begun; rate 95 per minute, high and quick, tension lowered.

As the weight upon the lever was kept in the same place for all of these tracings, the true character of the wave in Nos. 3 and 4 is not shown, as the

weight was not properly adjusted to the higher wave.

The fire-music from the closing scene of the "Walküre" also produced increased pulse-rate, with greater fulness and less tension. To one subject it brought up an image of flashing fire; to

TRACING 4.

From same subject, in hypnotic condition, during height of excitement, produced by same composition; 120 beats per minute, high, quick; tension low, marked irregularity in force. Tracing taken from the same person in normal condition, after violent exercise, shows almost exactly the same character.

another of waters rippling and sparkling in the sunshine; to another, of an ocean in which great breakers threw up glittering spray into the sunshine, the chief idea being in every case that of "sparkling."

The "Walhalla" motive, played in full, at first slowed the pulse and raised the tension; later, almost doubling the rate and lowering the tension. To the subject it gave a feeling of "lofty grandeur and calmness," and this in turn brought back the experience of mountain-climbing made years before, together with the mental state produced by the contemplation of a landscape of "lofty grandeur."

The music of the scene in which Brünhilde appears to summon Sigmund to Walhalla produced a very marked change in the pulse, which was made slow, irregular in rhythm, and very small. The respirations were decreased in rate, and became gasping; the face became pale, and covered with cold perspiration. The feeling described by the subjects was that of "death." No definite impression could or would be described.

The effect of single chords in certain relations produced wonderful effects. If during the height of excitement caused by the "Ride of the Walküre," in the key of B major, the chord of B minor was suddenly and loudly played, a most remarkable change was produced in the subject. In the case of the physician all excitement suddenly ceased, the subject's face became ashy pale, and covered with cold sweat; the pulse-rate dropped from 120 to 40 per minute, and became very irregular, soft, and small; the respirations were decreased in number, and became sighing in character. The whole picture presented was one of complete collapse, so that all who saw it were alarmed. On being awakened the subject said that he had been oppressed by a horrible fear, because "everything had suddenly seemed to come to an end."

This experiment was repeated many times, with always the same result. Upon the other subjects a similar effect was produced, with the same sensations, but of less intensity. It is to be remembered that none of the others could be put into so complete a state of hypnosis as this one subject. The same chord played in any other relation than the one mentioned produced no effect whatever.

Many experiments similar to these were tried, and from the results obtained it must be conceded that music is capable of producing remarkable physiologic effects in persons in the hypnotic state. These changes are most marked in the circulatory system. The action of the heart may, on the one hand, be doubled, or on the other decreased two-thirds of its rate almost instantly, a change that cannot be produced by drugs or by any form of suggestion. At the same time the other characters of the pulse are correspondingly affected. The rate and character of respiration can also be greatly changed, and the vasomotor system is also apparently under musical influence.

Other curious effects were also met with in the course of the experimentation. Certain chords produced in one subject, whenever they were sounded in certain combinations, most marked and painful contractions in the muscles of the legs, of so intense a degree as to cause pain for hours afterward. It was found, moreover, that the power of music was stronger than that of word-suggestion. One patient was thrown into a state of hyperesthesia by the playing of the overture to "Tannhäuser." When given a suggestion that a needle run into his arm would cause no pain he shrieked loudly because of intense pain produced by simple contact of the blunt end of the needle with the surface of the body. At all other times the spoken suggestion produced complete anesthesia. Connected with the hyperesthesia was also an exaggeration of the tendon-reflexes.

It was also found that as a means of producing the hypnotic state music is far superior to the ordinary methods. Different compositions seem to vary in power; as, for instance, one subject could be hypnotized only by the "Pilgrims' Chorus" from "Tannhäuser." Usually before the fifth measure was reached he would be in a complete hypnotic condition; and by no other means could this be accomplished so quickly and so perfectly. It mattered not where the subject was, or what he was doing at the time, even if in another part of the house; this piece of music, as soon as he had perceived it, had an irresistible power over him. It became necessary finally to oppose this effect by means of word-suggestion, in order to release him from its influence.

Having been told by a physician who was present at some of the experiments described, of a case in his knowledge in which certain combinations of tones in orchestral performances produced sexual

orgasms, an attempt was made to ascertain what effect could be produced upon the sexual function by music popularly supposed to be suggestive. The passages from "Die Walküre," "Tristan and Isolde," etc., long severely criticised because of supposed character in this respect, were found to produce only feelings of "longing," "frenzy," etc., but never exciting any sexual desire or suggestion. By the aid of word-suggestion, such effect could be produced, and the emotions of "longing," etc., could be made identical with the physical desire; but never did music of its own accord arouse such a state. And in this connection it may be said that music never directly aroused any purely physical state, as hunger, thirst, fatigue, etc., but gave birth primarily to soul-states.

The first effect of the music was always the production of a pure emotional state; and this emotion brought up in the subject's mind, through the power of association, a perfect and realistic reproduction of some past experience most closely connected above all other experiences with this emotional state. This was always purely personal. If the music produced the feeling of "death," as did some of the Wagner passages, the experience brought up was always that one death which had most deeply touched the subject's emotional life. The physiologic changes in circulation, etc., were partly the direct outcome of this emotion, and partly the result of the secondary experience. The difference in the effects of these two factors could almost always be noted. Thus, for example, the "Walhalla" motive: when first played it produced increased fulnesss and tension of the pulse, the subject breathing deeply but quietly. As the association of the mountain-climbing rose above the mental horizon the pulse became quicker, with lower tension, and the respirations became increased in rate and force. All of the experiments produced results that could be explained in this way, with the exception of the production in one individual of muscular cramps and hyperesthesia. These conditions seemed to have no relation to the emotional state or to the secondary state of association. As the subject put it: "The music simply did it, and that was all there was to it."

The account of the total number of experiments made in this line might prove interesting reading, as the results certainly in themselves were interesting; but in each case the effect was practically corroborative of the foregoing. It is certainly neither desirable nor safe to draw important conclusions from results obtained in such a small number of cases, and I make this report only in order to call attention to the results obtained in one set of subjects. As the difficulties attending hypnotic experimentation are many, the work necessary to establish these results more firmly can be done only by those who have unusual opportunities for investigation in this line. To such I leave this field. Moreover, if music has any therapeutic value, it must to a chief extent be the effect of suggestion; so that, if anything is to be hoped for from its power it must be along this line. Further investigation must show this.

In conclusion, I would say that experiments of this nature may be attended by danger. The symptoms of collapse developed at times, with the accompanying intense emotional shock, might be increased beyond the point of safety. In individuals of strongly musical and emotional natures disastrous results are not inconceivable. There is also danger of establishing an hypnotic habit. In one subject, to whom the intense emotions and vivid experiences were very pleasant, the power of self-hypnosis under the influence of music was practised even in public concerts. The habit was broken by means of word-suggestion. It is necessary, therefore, that hypnotic experiments be conducted with great care, and the possibilities always borne in mind.

CHRONIC INFLAMMATION OF THE SEMINAL VESICLES.[1]

By GARDNER W. ALLEN, M.D.,
SURGEON IN THE GENITO-URINARY DEPARTMENT, BOSTON DISPENSARY.

I FEAR the title of this paper may suggest the idea of rare and obscure disease in an inaccessible situation, of interest only to specialists; but I hope to be able to show that we have within reach a means of interpreting many puzzling symptoms in a large and important class of cases.

The apparent indifference on the part of the profession at large, and even of specialists, toward the vesiculæ seminales is surprising, and it is only within a few years that they have begun to attract in some degree the attention they deserve. Mr. Jordan Lloyd, of Birmingham, England, in 1889, was the first to give them full recognition, and to demonstrate their importance when diseased. In Gouley's *Diseases of the Urinary Apparatus* a chapter is mainly devoted to the subject, which is particularly valuable for its exposition of the anatomy, physiology, and pathology. About a year ago Dr. Eugene Fuller, of New York, read an article that gives a more complete and detailed description than any other that has yet appeared of vesicular inflammation, and especially of its treatment, which he has developed and put on a practical basis.

It may be well to recall a few anatomical points:

"The vesiculæ seminales are two irregularly convoluted tubes, lying one on each side of the under

[1] Read at the Annual Meeting of the Massachusetts Medical Society, Boston, June 13, 1894.

surface of the male bladder. . . . They vary greatly in size, . . . but average perhaps two inches in length, as they lie on the bladder. If dissected off and straightened out, they are found to be two or three times this length. . . . The vasa deferentia pass . . . along the inner sides of the two vesiculæ and unite at an acute angle with the ducts of the seminal vesicles to form the common (ejaculatory) ducts. Just before this union takes place each vas deferens widens out into a tortuous sac or ampulla, which closely resembles in structure the seminal vesicle itself." (Thorndike.)

Inflammation of the seminal vesicles, variously called spermato-cystitis, gonecystitis (Gouley), and seminal vesiculitis, is analogous to salpingitis—that is to say, the vesicles, according to Lloyd, are the analogues of the Fallopian tubes. It is rarely, if ever, a primary affection. It is almost always secondary to urethritis, generally gonorrheal, or it may be, though rarely, secondary to tuberculosis or malignant growth in the vesicle. It is commonly, but not necessarily, present in cases in which there is or has been epididymitis.

Acute inflammation is almost always of gonorrheal origin; it is similar to epididymitis in a general way, and rarely advances to suppuration. The symptoms are substantially those of acute prostatitis: local pain and heat, spasmodic contractions of the perineal muscles, etc.; and this has probably led to mistaken diagnosis in many cases.

But it is the more common and more important chronic inflammation that we have now chiefly to consider. This may result from the acute form first mentioned, but is usually chronic, or at most subacute, from the beginning. In this case the source of the trouble may be gonorrheal prostatitis or cystitis, or a posterior urethral catarrh resulting from congestion of the prostatic portion brought about by prolonged and repeated sexual excitement.

In chronic vesiculitis we have a train of symptoms commonly enough observed and not always peculiar to this affection, and, therefore, generally attributed to other causes. There may be a chronic urethral discharge, with shreds in the urine; or vesical irritability with frequent micturition, not always present and often slight, but sometimes more marked, with urine more or less turbid and containing shreds and clumps of pus and blood. In a large majority of cases there is some disturbance of the sexual function, showing itself by the presence of one or more of the following symptoms: deficient erectile power, with or without diminished desire, spermatorrhea, frequent emissions, occasionally hemospermatism, viscid discharge from the meatus at stool, and the various local subjective sensations, as well as the general nervous and mental symptoms peculiar to sexual neurasthenia. A burning feeling in the perineum and along the urethra is one of the more common of the subjective sensations. Spermatic colic, a pain in the region of the vesicle, due to occlusion of the duct, and sometimes accompanying ejaculation during coitus or an emission, is an occasional symptom.

It might seem that with symptoms so varied and not wholly characteristic the diagnosis would not be easy, and in fact, it can only be made by rectal examination. When a sufficient number of examinations have been made to thoroughly familiarize one with the topography of the region under varying conditions, the diagnosis is not difficult in a well-marked case. The vesicles, or at least their lower parts, are usually within easy reach of the forefinger, though in some cases they are more difficult to get at. The patient with a moderately full bladder should stand with the body bent to a right angle at the hips, with the knees straight, the feet spread apart and the hands resting on a chair. The forefinger is passed slowly and gently through the anus and over the prostate, which should be examined and its condition noted as to size, form, and consistence. According to my experience, it is rather small in a large proportion of these cases. Just beyond the lateral lobes of the prostate, lying in the sulcus between it and the distended bladder, and extending obliquely outward and backward toward either side, are the seminal vesicles. The examination is aided by exerting counter-pressure with the free hand over the inguinal region of the side that is being explored. It is further aided in cases in which the vesicles are difficult of access by placing the foot corresponding to the examining hand on a chair and bracing the elbow against the knee; in this way considerable force can be exerted by which to overcome the resistance of the perineal muscles.

When normal the vesicles are soft and scarcely appreciable to the touch, sometimes not at all; but when diseased they are plainly felt. One or both may be affected. Sometimes they are nodular and indurated, resembling somewhat a twisted and knotted cord. Again, they are much distended, and form smooth, rounded bodies that on palpation are felt to contain fluid. In the latter case the vesicle is often so closely attached to the prostate as to be easily mistaken for it—that is, it seems to form the posterior border of the lobe on that side, but with care fluctuation can be detected and a line of demarcation between the vesicle and the prostate can be made out, similar to the line of demarcation between the testicle and the epididymis in acute inflammation of the latter organ. Sometimes the vesicles are much enlarged and dilated, but not distended, and form soft, fluctuating sacs. Gouley speaks of shriveling of the vesicles, generally asso-

ciated with prostatic enlargement; but a diagnosis of this condition could hardly be made during life.

In acute inflammation, of course, the swelling is greater, the perivesicular tissue being involved; it is diffused, doughy, and hot, and is extremely sensitive to the touch. The sensation in the chronic affection varies in different cases. Sometimes there is decided pain and tenderness on pressure, but these are usually not marked, unless the finger bears down quite hard; more commonly a disagreeable sensation is described, which occasionally causes faintness. Sometimes there is only slight sensitiveness, even on firm pressure. By means of this pressure the contents of the vesicle are emptied into the deep urethra, and, if in considerable quantity, will ooze from the meatus and will in any case appear in the urine passed after the operation. The fluid thus squeezed out varies in different cases from a thin liquid, resembling skimmed milk, to a thick, gelatinous substance, sometimes containing inspissated particles and appearing in the urine in the form of clumps and shreds. Microscopic examination of the thin fluid shows only a little epithelium and a few dead spermatozoa; the thick substance often seems to consist of masses and bands of fibrinous material, entangled in which are sometimes a few, sometimes great numbers of motionless spermatozoa. When normal vesicles are squeezed nothing will appear, except perhaps a very slight turbidity of the urine.

With respect to prognosis, this must necessarily, a few years ago, have been regarded as decidedly unfavorable; but owing to recent progress in treatment, it is already safe to say that improvement may be expected in a majority of cases, although more extensive data than are now attainable will be required before a reliable opinion can be formed as to the chances of complete recovery.

The treatment is simple, but requires a good deal of judgment, chiefly to avoid overdoing. It consists in pressure with the end of the forefinger, reaching as far up toward the free end of the vesicle as possible, and then stripping it down toward the duct. In this way the abnormal secretions are removed and are not allowed to accumulate. Sometimes the ducts are obstructed by inspissated material or by concretions called sympexia, and several treatments are necessary to clear them; or a sound may be passed into the bladder and the vesicles pressed against it, as advised by Gouley, the obstruction being in this way more easily dislodged. The danger in overdoing the treatment is of bringing on an acute exacerbation by too active manipulation, which I was unfortunate enough to do in one of my first cases. As some patients are much more susceptible to reaction than others, great caution should be observed at first, only gentle pressure being used, and the effect carefully watched. As to frequency of the sittings, Gouley recommends daily treatment, but Fuller thinks it should not be repeated oftener than once in four days. The effect of the treatment is not, as a rule, immediately apparent, although in some cases marked improvement is soon noticeable.

It is generally necessary to keep up the treatment for several weeks, sometimes even months, before the vesicles are restored to a normal condition. This is brought about by keeping them empty until their muscular walls recover their tone and they are able to properly carry on their functions. This process is appreciable to the physician in a gradual decrease of the swelling and softening of the induration, until after a while the vesicles apparently disappear—that is, they become as difficult to feel as in the normal state. At the same time the sensitiveness steadily diminishes and the amount of fluid expressed grows constantly less until there is none. I have noticed, also, in a few cases that the prostate, which is necessarily massaged more or less during the manipulation of the vesicles, has undergone considerable change, increasing in size when atrophied, and assuming a more nearly normal consistency. In the course of the treatment a gradual improvement in the general health and in the nervous condition, or a diminution in the frequency of emissions, or, in general, an abatement of whatever symptoms secondary to the disorder have been prominent in each particular case may be looked for. No medicinal treatment is required, unless indicated by special symptoms.

Since the latter part of January, when, through Dr. Fuller, whose methods I have closely followed, I became especially interested in this subject, I have examined seventy-four cases with reference to the condition of the seminal vesicles. In all of these there was reason to suspect that disease of the vesicles might exist. In fifty-five a more or less abnormal condition was found, both vesicles being affected in thirty-eight of them. In two cases the trouble was acute, in three, subacute, and in the remainder it was chronic. In the acute cases, in two of the subacute and in thirty-one of the chronic cases there was a history of gonorrhea. Of twenty-three cases, all chronic, in which I have been able to follow up the treatment sufficiently long to get definite indications of its effect, there has been improvement in nearly all. In a few it has been marked and speedy, some having practically recovered; in the majority it is still too soon to give final results, while a very few have been disappointing.

Since this paper was written I have had the pleasure and advantage of hearing a very exhaustive article on the subject by Dr. R. W. Taylor, of New York, who, at the same time showed by means of an

anatomical specimen that the vesicle is convoluted and doubled on itself in such a way that stripping the organ with the finger toward the duct would empty only a portion of it, together perhaps with the vas deferens. He believes that the dilated portion or ampulla of the vas deferens is often mistaken for the vesicle. He is, in fact, somewhat skeptical as to the efficacy of the treatment by pressure. However this may be, it is certain that the large amount of fluid squeezed out and the progressive diminution in the swelling observed in many cases show that the pressure has been effectual. In view of these facts, which seem to be not wholly consistent, a few considerations suggest themselves.

1. The fluid in a distended vesicle, subjected to pressure, would escape at the point of least resistance, which would be the natural outlet, no matter how tortuous, unless the wall of the vesicle were ruptured by violence. Simple pressure on such a blind sac would seem better than an attempt to strip the vesicle down toward the duct.

2. The slow and unsatisfactory progress of a few cases may be due to the difficulty of emptying such portions of the vesicle which may in these cases be the chief seat of disease.

3. In some cases the ampulla of the vas deferens may alone be affected, when the stripping process would be easy and effective.

4. Disease of the vas deferens may possibly be of more importance than that of the vesicle itself, obstructing as it does the direct road from the testicle.

5. Simple massage of the vesicles may play an important part in the treatment.

CLINICAL MEMORANDUM.

POTASSIUM NITRATE IN THE TREATMENT OF PHLEGMASIA ALBA DOLENS.

BY GREGORY H. HOVNANIAN, M.D.,
OF WEST FULLMAN, ILL.

WITHIN the past month it has fallen to my lot to treat three well-marked cases of phlegmasia alba dolens with potassium nitrate with such gratifying results as to seem to justify publication.

Mrs. H., twenty-three years old, was delivered of her first child by her family physician with instruments, and sustained extensive lacerations of the cervix uteri and perineum, which at the time were not repaired, but were left for a secondary operation. Twelve days after delivery she complained of pain and heaviness in the left leg, and within three days there developed well-marked phlegmasia. On the fourth day of this complication I saw the patient in great agony, with a temperature of 105.2,° a pulse of 130, and respirations 25. The limb was so turgid and swollen that there seemed to be great danger of gangrene or rupture. The woman was at once given morphin sulphate, gr. $\frac{1}{8}$, hypodermatically, and her limb was wrapped with cotton and placed on a feather pillow at a very obtuse angle. I then prescribed a solution of potassium nitrate in water representing five-grain doses, to be given every hour until my return. Seven hours later I found my patient in better condition, with a temperature of 103°, a pulse of 112, and respirations 22, and with less pain and discomfort. The swelling seemed to be less tense and the veins less engorged. The nitrate was continued as before until morning, when I found her in yet better condition. She had slept well during the night, although she had been wakened regularly for her medicine. Her temperature was 100°, her pulse 95, her respirations 20. The swelling was reduced to less than half, and the returning circulation was fairly well established. There was no pain whatever, and but slight tenderness on pressure. The medicine was continued every two hours during the day, until I saw her late in the evening with a temperature of 99°, a pulse of 90, and respirations 18. The swelling had almost entirely gone, and everything was in good condition. The nitrate was continued for two days in smaller doses, and at longer intervals, and then discontinued.

The second case is more interesting because of a relapse, in the course of which potassium nitrate was given a more thorough test.

Mrs. S., thirty-five years old, after a normal labor, lasting eight hours, was delivered of her fourth child. She sustained no laceration of the cervix uteri, but a very slight one of the perineum, necessitating no stitches. According to the statement of the attending physician everything progressed normally until the ninth day after delivery, when symptoms of phlegmasia appeared, and in a few days developed into a typical case. Opiates and laxatives were administered, and evaporating lotions applied to the affected limb without avail until the fourth day, when I saw the patient in consultation. At this time the temperature was 105°, the pulse 120, the respirations 22. The limb was greatly swollen and turgid, and there was besides abdominal tenderness and tym-

pany. Previous to my visit the attending physician, thinking gangrene of the limb imminent, suggested the necessity of longitudinal incisions deep into the limb, but the family would not consent, and requested a consultation. After a thorough examination of the patient's general condition, which was rather unfavorable on account of a weak heart and extreme nervousness, I advised the postponement of surgical interference, and suggested a thorough trial of potassium nitrate. The attending physician assented, and asked me to take charge of the case, as he was obliged to go out of town for a few days. I ordered potassium nitrate, gr. v, every half-hour; meantime I discontinued the evaporating lotion, and wrapped the limb in cotton, and put it at a very obtuse angle on a feather pillow. Eight hours later I found the patient much improved. The temperature was 101.4°, the pulse 100, the respirations 20; the swelling had decreased, and there was less pain. The woman had slept about three hours for the first time in three days, and felt refreshed and hopeful. The abdominal tenderness and tympany had not improved at all (these were undoubtedly due to constipation), yet I did not dare open the bowels from fear of disturbing the limb. I, however, reduced the nitrate to five grains every hour. The following morning I found the woman still more improved, the temperature being 99.2°, the pulse 90, and the respirations 19. The swelling was mostly gone; there was no pain; and all was progressing well, except the abdominal symptoms, which were rather increased and caused much complaint. The nitrate was reduced to five grains every two hours, and small doses of calomel were ordered every half-hour until the bowels moved. During the afternoon the bowels moved twice, with much relief to the abdominal distress. In the evening I found the woman in a very comfortable condition, the swelling fast disappearing, and she out of danger. The next day the nitrate was given every three hours, and the swelling had almost entirely disappeared; but in the evening, in placing her upon the chamber, they wrenched her affected limb, and during the night she suffered excruciating pain. Early in the morning I was sent for, but being away from home I did not see the patient until two o'clock in the afternoon. I was surprised to find her in as bad a condition as on the first day I saw her. The temperature, pulse, and respirations were as high as before, and she seemed to have much more pain, so that I suspected a fracture or dislocation complicating the relapse; but the swelling was so tense that no examination could be made. I ordered opium-suppositories to control the bowels, and put her on five-grain doses of potassium nitrate every hour as before. In the morning I was gratified to find the temperature almost normal, the pain and swelling almost gone, and the patient in a fair way to recovery. After this the nitrate was reduced gradually as before, and she made a rapid recovery.

The third case was a comparatively mild one, and made its appearance earlier than the foregoing two cases, although it did not respond to the treatment so readily.

Mrs. J., thirty years old, after a normal labor, was delivered of her third child without any laceration of the parts. On the third day she had an abundant flow of milk to the breasts, which caused her considerable distress. This was soon checked by massage and laxatives, but on the sixth day the right lower extremity began to swell, and there developed a phlegmasia. The limb was wrapped in cotton, and put at an obtuse angle on a feather pillow, and the woman was given potassium nitrate, gr. v, every hour. Within twenty-four hours the active process was checked, but the pain and swelling were not reduced; nor was the temperature, which was 102°. I increased the dose of the nitrate to five grains every half-hour. This was continued for eighteen hours, after which the swelling and pain began to subside, and entirely disappeared in four days.

It is surprising to note how rapidly the temperature, pain and swelling were reduced by the repeated doses of potassium nitrate, even when antithermics, opiates, and evaporating lotions had proved entirely useless. I did not notice any change in the action of the heart in any of these cases, although the urine was very much increased in quantity. After the temperature was reduced, it had a tendency to remain subnormal for a few days, being 97.8° on an average, and in one case remaining 97.4° for three days, but no chilly sensation was complained of.

I consider friction of the affected limb, as recommended and practised by some, very dangerous, as a blood-clot may be detached and carried to the heart or some other organ, and disastrous results follow. I therefore consider absolute rest and a position of the limb which will slightly relax the vessels essential for safe recovery.

HOSPITAL NOTE.

INHALATIONS OF OXYGEN IN TWO CASES OF OPIUM-POISONING.

[Service of Dr. S. S. Stryker, Presbyterian Hospital, Philadelphia.]

By P. M. Ashburn, M.D.,
resident physician.

Seeing in The Medical News of July 21st an extract from the *Lancet* of June 2, 1894, on the use of inhalations of oxygen in the treatment of opium-narcosis, I thought it might prove interesting to relate two cases of opium-poisoning in which oxygen-inhalations were employed.

On June 11th there was admitted to the receiving ward, at about 1 A.M., a child of fourteen months, in deep coma. The mother stated that she had been taking laudanum for the relief of pain, and had left the bottle standing on a window-sill, where the child had gotten it and drunk the contents. The mother could not even approximate the amount taken. The child had drunk the liquid at about 8 P.M., and was treated at home, but grew steadily worse and was sent to the hospital. On admission she was deeply comatose, and completely relaxed, with all reflexes absent, the pupils minutely contracted, the respiration rapid but very shallow and feeble, the pulse rapid, small, and weak. She was given a hypodermatic injection of atropin sulphate, gr. $\frac{1}{100}$, strychnin sulphate, gr. $\frac{1}{100}$, and caffein citrate, gr. $\frac{1}{4}$, which was repeated in fifteen minutes, with no apparent effect, and as the child was sinking and its respirations ceased entirely, resort was had to oxygen-inhalations and artificial respiration. The effect was immediate, and

after six or eight respirations the breathing was spontaneous, full and deep, and the pulse much stronger and fuller. Two gallons of the gas were given at this time, and two gallons every half-hour for the rest of the night. The recovery was uninterrupted and complete.

The second case was that of a man of fifty years, who was admitted June 30th, in deep coma, with minutely contracted pupils, face and hands pale, cool and moist, arms and legs completely relaxed, respirations very slow and shallow, and pulse very soft and compressible. There was no odor on the breath; the urine contained albumin. The temperature was 96.4°, the pulse 124, the respirations 4. The history was that the man had not been feeling well and had retired to his room at 2 P.M., and was not seen again until found in coma almost five hours later. In his room was found a note of farewell and two empty bottles that had contained laudanum. The one was a three-ounce bottle; the other was not brought to the hospital, and its size is not known. On admission the patient was given hypodermatically atropin sulphate, gr. $\frac{1}{30}$; strychnin sulphate, gr. $\frac{1}{10}$; and caffein citrate, gr. jss. There was considerable delay in getting oxygen, and before it arrived the respirations had ceased and the pulse was very bad. Artificial respiration was meanwhile employed, and when the oxygen arrived its administration was at once begun. After a very few breaths of the oxygen the respiration was spontaneous, and the change in the pulse was most marked and gratifying. Almost immediately the pulse became slower and strong and full. The respirations rose to 18 per minute, and were full and deep. Fifteen gallons of oxygen had been used, a considerable part probably being wasted.

At the end of three-quarters of an hour the respirations were again becoming slow and shallow and the pulse weak, so that every half-hour the man was ordered at least two gallons of oxygen, and as much more as might be necessary to get his pulse and respiration in good condition. Sometimes two gallons sufficed, and at other times ten gallons were necessary.

The next day the patient's condition was much improved, but his temperature was high, at one time reaching 104°. The patient had also been getting a grain and a half of caffein citrate every hour for a time, and then every two hours. As the elevation of temperature was ascribed in part to this drug, and as it did not seem to do much good, it was withheld. The patient was thus getting nothing but the oxygen. The urine was found to be dark, of a specific gravity of 1022, and to contain albumin and hyaline and granular tube-casts.

The man came entirely out of his coma, but his breath became urinous and he developed symptoms of uremia, with almost entire suppression of urine. His bowels were moved freely, however, and he seemed to be improving, but died suddenly on the third day after his admission, his temperature a short time before death being 103°.

The autopsy disclosed the existence of chronic parenchymatous nephritis. There was edema of the brain, and almost complete consolidation of both lungs, apparently due to hypostatic congestion, though repeated and careful examination of the lungs before death had shown no abnormal signs other than slightly enfeebled breath-sounds and a few moist râles at the apices.

While it may not appear from the report of these two cases that the oxygen played a very important part, or that it was markedly beneficial, such was certainly the case. The improvement in the pulse and respiration under its use was so rapid and so manifest that all who saw it could not but be convinced. The death of the second case was probably due to the kidney-lesions, with the secondary conditions present in the lungs and brain, and the first marked improvement would in all probability have continued had the kidneys been normal.

THERAPEUTIC NOTES.

By SOLOMON SOLIS-COHEN, M.D.,
of Philadelphia;
Professor of Clinical Medicine and Therapeutics in the Philadelphia Polyclinic; one of the Physicians to the Philadelphia Hospital, etc.

VII.

BENZONAPHTOL AND BISMUTH SALICYLATE IN SUMMER DIARRHEA.

The term summer diarrhea is here used to include the various forms of gastro-intestinal disturbance occurring during warm weather, and especially characterized by frequent, loose, or even fluid discharges from the bowel: sometimes attended with pain; sometimes attended with fever; sometimes associated with nausea and vomiting.

While the pathology and etiology of these various forms of disturbance of the alimentary canal vary in particulars, the general factors are the same; an indiscretion in diet, special or general, remembered or forgotten; over-heating or over-exertion in the heat; irritation or inflammation of the gastro-intestinal mucous membrane in whole or in part; bacterial activity; intoxication by absorption of noxæ from the intestines. After the alimentary canal has been cleansed of irritating materials by the most available means, which may be, according to circumstances, lavage of the stomach, irrigation of the bowel, or the administration of a purge, usually calomel, or a mixture of castor-oil and spiced syrup of rhubarb (equal parts); and after the diet has been duly regulated, I have observed very satisfactory results from the administration of the following combination:

Benzonaphtol Bismuth salicylate Dover's powder	of each, 5 grains.

In capsule, cachet, or powder.

To an adult, one capsule is given every three hours, or as necessary. It is rarely needful to exceed four doses in the twenty-four hours. To children, the same preparation may be given in reduced dosage; thus to a child of two years I have given:

Benzonaphtol	2 grains.
Bismuth salicylate	2 "
Dover's powder	½ grain.

In the mildest cases benzonaphtol alone has proved efficient, and in many cases the opium is unnecessary; but, as a rule, the combination of the three ingredients in the proportions stated is more promptly efficacious, if present experience can be relied upon, than any other routine treatment I have used. This is the second season during which I have employed it.

A word may be added as to diet. It is best, under the conditions stated, to make a complete change in the food, whether of child or of adult. If a child is taking milk in any form—sterilized, boiled, predigested, or plain—all milk should for the time being be cut off. It will not harm a child to go without food for a day or two, but as parents cannot readily be brought to see this, it is best to give some substitute. Barley-water and (home-made) beef-juice are the most available. They may be given alternately in small quantities—from two to four ounces of barley-water; from one to four drams of beef-juice, freshly prepared, every third or fourth hour. If a child has been sick for some time and is much run down, alcohol (from ten to twenty drops of brandy or whiskey) may be added, or given with water between food-times. Smaller quantities of beef-juice, given more frequently, may sometimes be called for by the special conditions of a particular case. If a child is taking various kinds of food, but not much milk, boiled milk with pancreatic powder may be given, as with adults. As a rule, however, it is advisable to avoid milk until the alimentary canal is rendered aseptic, for milk is quite liable to undergo deleterious change after being swallowed, as well as before—a point that is frequently overlooked.

In the case of adults it is usually safe to give boiled milk; in some instances adding sufficient pancreatin and sodium bicarbonate to accomplish artificial digestion in the stomach. I usually prescribe two and a half grains of pancreatin and seven and a half grains of sodium bicarbonate (*i.e.*, one dram and three drams respectively, divided into twenty-four powders, in waxed papers), to be dissolved in an ounce of cold water, and the solution added to a teacupful of warm (previously boiled) milk. This is taken every third hour. When the patient refuses milk, or it is for other reason objectionable, beef-juice, barley-water, tea, coffee, sherry and water, whiskey and water, claret and water, and the like may be given, in small quantities. In most cases the whole question of alimentation is a negative rather than a positive one—to avoid food that will ferment or decompose, or otherwise give rise to irritating products or toxins; for recovery is usually so prompt that the problem of maintaining nutrition does not arise. It is usually best to give water freely—aërated water being preferable.

NEW INSTRUMENTS.

TREATMENT OF URETHRAL VEGETATIONS BY MEANS OF A CIRCULAR CUTTING CURET.

By JOHN B. DEAVER, M.D.,
of Philadelphia.

A definite knowledge of the presence of urethral growths can only be obtained by inspection of the canal. This is now most readily accomplished by the electric-light urethroscope, a valuable instrument, not only in the diagnosis of chronic urethral lesions, but in the treatment of many as well. That the urethroscope is a necessary instrument in the practice of genito-urinary surgery can no longer be questioned.

The removal of certain forms of small urethral growths can be accomplished by local applications made through a urethroscopic tube, while in the case of larger growths, and especially if they be sessile in character, more radical treatment will be required. For the latter purpose I have devised the instrument shown in the accompanying illustrations—a circular cutting curet, which is introduced through a urethroscopic tube.

The instrument consists of a circular blade, with two notches on the free border, opposite each other, and which engage the urethral vegetations. The blade is fastened to the end of a rod mounted in a handle that fits snugly into the proximal end of the urethroscopic tube, thus steadying the curet during manipulation. It is important to introduce as large-sized a tube as the urethra will permit, the object being to put it on the stretch, thus facilitating the removal of the growths.

As the normal urethra varies in caliber, it is necessary to have a number of instruments of different sizes. The hemorrhage following the removal of the vegetations, which is sometimes free, is easily controlled by the application of a solution of silver nitrate, the strength of which will vary according to circumstances.

1. Deaver's urethroscopic tube, with circular cutting curet *in situ*.
2. Deaver's circular cutting curet.
3. Deaver's urethroscopic tube, with stylet.

The only opportunity I have had of using this instrument has been in two cases of venereal warts within the urethra—the histories of which I shall briefly relate:

Case I.—A. T., aged thirty-two years, came under my notice with a chronic urethral discharge, for which he had been treated without relief. He gave a history of having had two attacks of gonorrhea. Urethroscopic examination showed, in addition to an infiltration of the anterior half of the pendulous urethra, the presence of a number of venereal warts, extending backward from the meatus four and a half inches. The urethra was cocainized, and the warts were removed at one sitting with the circular curet. The bleeding was free, but was controlled without difficulty by the application of a

solution of silver nitrate. The patient reported a week afterward, when a second examination showed the urethra free from foreign bodies.

Case II.—S. K., aged twenty-eight years, with a history of three previous attacks of gonorrhea, was referred to me by his physician for urethroscopic examination to determine the cause of a chronic urethral discharge. The examination revealed the presence of a stricture of large caliber, three and a half inches within the meatus. Behind the stricture the urethra to the peno-scrotal junction was the seat of large sessile venereal warts. These were readily removed by the circular curet, the stricture having been previously divided by dilating internal urethrotomy.

MEDICAL PROGRESS.

Successful Excision of a Perforated Ulcer of the Duodenum.—Dean (*British Medical Journal*, No. 1741, p. 1014) has reported the case of a woman, twenty-seven years old, who for about two weeks had suffered from pain in the chest and at the pit of the stomach. There had been some nausea and vomiting and the bowels had not been moved for seven or eight days. About twenty-four hours before coming under observation the woman had suddenly become worse, complaining of severe pain at the pit of the stomach and of a sensation of intense weakness. This was soon followed by vomiting repeated at frequent intervals. The pulse was 120, feeble and regular. The respirations were rapid and irregular in force and rhythm. The tongue was slightly furred and dry. There was uniform tenderness over the whole abdomen; the distention was moderate in degree and the percussion-resonance was increased. The temperature was 100.6°. It was thought that there existed mechanical obstruction of the bowel, with general peritonitis, and it was decided to operate at once. An incision, about three inches long, was made below the umbilicus. On opening the peritoneal cavity a quantity of purulent fluid escaped, and coils of intestine, somewhat distended, intensely congested and covered in places with flakes of lymph, protruded through the wound. No evidence of mechanical obstruction could be found. The incision was therefore extended upward and flakes of lymph were found in the region of the gall-bladder. In the center of one of these flakes gas-bubbles were noticed, forming a kind of froth. A probe introduced into the froth passed into a cavity which was found to be the duodenum, the perforation being situated on the anterior aspect about three-quarters of an inch beyond the pylorus. Around the perforation distinct induration could be felt. This area was excised by means of scissors. The portion removed was elliptic in shape, measuring one and a quarter inches in its long axis, which was parallel with the transverse axis of the gut. The portion excised was found to include the ulcer and a margin of healthy mucous membrane. In the center of the ulcer was a perforation about 2 mm. in diameter. The floor of the ulcer was white and the edges were bound by apparently healthy mucous membrane. The elliptic opening thus made into the duodenum was then closed by means of Lembert sutures. The peritoneal cavity was washed out with a weak boric-acid solution and well sponged, and the wound was closed by stitches passing through the whole thickness of the abdominal wound. The patient was nourished per rectum by enemata and suppositories for seventeen days. She rapidly improved, and was given liquid food by the mouth on the eighteenth day and solid food on the twenty-eighth day. Thirty days after the operation the patient was walking about and eating ordinary food. Twenty-five days later she presented symptoms of intestinal obstruction due to a band. The abdomen was opened and the constriction, which was found to involve the ileum about six inches above the cecum, removed. The woman recovered slightly from the shock of the operation, but never rallied thoroughly. She gradually became weaker, and died about thirty-six hours after the operation. Upon post-mortem examination a considerable amount of lymph was found upon the intestines and the peritoneal cavity contained a quantity of turbid fluid. About three inches above the attachment of the band to the small intestine was a perforation from which intestinal contents had escaped. A little higher up was another perforation. On opening the intestine each perforation was found to be the center of a small ulcer. The ulcers were evidently of acute and recent formation, while there were several other necrotic patches within eighteen inches of the obstructed point. For about half an inch from the pylorus the duodenum was thinner than normal and the peritoneum over it was puckered. The duodenum was quite healthy and presented no traces of past or recent ulceration.

An Unusual Form of Anal Tuberculosis.—Kramer (*Centralblatt für Chirurgie*, 1894, No. 16, p. 363) has reported the case of a man, thirty-nine years old, who within a period of a year had presented cough, with scanty expectoration, and pain in defecation, with some tenesmus, and with slight hemorrhage at times. An ulcer, about an inch in diameter, had formed in the region of the anus and despite topical treatment had progressively increased in size. There was pain preceding and during defecation, together with some hemorrhage and with failure of nutrition, emaciation, and loss of strength. Physical examination disclosed impairment of the percussion-resonance and fine râles at the summit of the right lung. The inguinal glands were slightly enlarged on both sides. In the region of the anus there existed a fungous tumor, half as large as an ordinary apple, granulating upon its surface and secreting pus. It involved the parts to the right of the anus and extended to the internal sphincter. With a lens the granulations could be seen to be made up of small, grayish-yellow nodules. The ulcerated area was circular in outline; its margins were firm and not undermined; it was pale bluish-red in color; the surrounding tissues were not involved; and there was no indication of a fistula communicating with deep-seated parts. In view of the suffering of the patient it was decided, after suitable preparation, to operate and the entire ulcer was duly excised, the right half of the external sphincter being included in the removal. The wound was sutured and dressed with iodoform and gauze and the bowel tamponed. Primary union resulted and the man was dismissed at the end of three weeks. The symptoms referable to the anus were permanently relieved, although death took place some months after the operation as a result of the pulmonary condition.

Histologic examination of the tissues removed disclosed the presence of tubercles and of tubercle-bacilli. The peculiar and unusual localization is attributed to the lodgment in an abrasion or fissure of the mucous membrane at the anus of tubercle-bacilli contained in swallowed sputum.

Degeneration of the Thyroid Gland in a Case of Arthropathic Psoriasis followed by Myxedema.—Sergent (*Bull. de la Soc. Anatom. de Paris*, 1894, fasc. No. 6, p. 180) has reported the case of a woman, fifty-five years old, who, ten years before coming under observation, had a generalized eruption of psoriasis in conjunction with other disturbances related to the menopause. The eruption disappeared in the course of a few months, but was soon succeeded by another, and in this way numerous attacks occurred; but finally there was no remission in the skin-lesion. The patient complained also of pains occurring paroxysmally, and referred especially to the small joints of the hands and feet and of the spinal column. The joints of the hands and feet became distorted and nodular, like those of arthritis deformans. The head became strongly flexed on the chest and could not be extended, efforts to do so giving rise to pain. The integument presented a livid, red hue, which was especially marked upon the arms and the thighs, where there was, besides, an abundant desquamation of large scales. In these situations the skin and the subdermal structures were infiltrated by a hard, smooth, and stiff edema, not pitting on pressure. The face was pale, the eyelids swollen, the expression fixed, the cheeks relaxed, the lips large and pendent. The intelligence was obscured and the memory impaired; the patient found difficulty in expressing herself and stuttered in speaking. All of the symptoms progressed slowly until death ensued. Upon post-mortem examination the lungs were found emphysematous and anthracotic; the pericardium was distended with a large quantity of fairly clear fluid; the heart was large and surcharged with fat; the aortic valve was slightly incompetent, and on the larger mitral leaflet was a patch of atheroma. The kidneys were in a state of parenchymatous inflammation. The thyroid gland was much reduced in size; the right lobe was relatively atrophied, while the left had almost entirely undergone calcareous degeneration.

Eight Splenectomies and One Ligation of the Splenic Artery.—At the Eleventh International Medical Congress, recently held at Rome, Tricomi (*Le Mercredi Médical*, 1894, No. 19, p. 232) reported eight cases in which he had extirpated the spleen for various morbid conditions, with a fortunate issue in all but one. In one there existed splenic leukemia. The proportion of colorless to red blood-corpuscles varied from 1 : 30 to 1 : 10. The spleen weighed a little more than five pounds. The patient died of shock four hours after the operation. In one case a wandering spleen was removed; the blood contained 1 colorless to 410 red corpuscles; the spleen weighed 14½ ounces. In a third case there was ectopia of the spleen; the organ was adherent to the parietal peritoneum in the right epicolic region; the proportion of colorless corpuscles was 1 to 380 red; the spleen weighed 15 ounces. In two cases there existed simple splenic hyperplasia; in one there was 1 colorless blood-corpuscle to 500 red, in the other 1 to 400; the organs weighed respectively more than 2 and more than 2½ pounds. Three cases presented malarial hyperplasia of the spleen; the proportion of colorless to red corpuscles was respectively: 1 : 350, 1 : 390, 1 : 470. The spleens weighed respectively 2 pounds, 2 pounds, and a pound and a half. In two of the operations median celiotomy was performed; in the others a curvilinear incision was made from the inferior border of the left seventh rib to the anterior superior iliac spine. In all cases the hilus of the organ was ligated *in situ* in three or four divisions; in one instance seven ligatures were necessary. In one case of splenic leukemia, in which the proportion of colorless blood-cells was 1 to 70 red, the splenic artery was ligated. The spleen underwent gradual gangrene, and death took place on the forty-fifth day after the operation.

Posterior Spinal Sclerosis with Homonymous Hemianopsia.—At a recent meeting of the New York Neurological Society, Dr. Frederick Peterson presented a married bricklayer, fifty years old, without hereditary taint. He had had a chancre twenty-eight years before, and for four years had noticed that his vision was growing dim, although fourteen years earlier he had had transient diplopia for three weeks. The man had been under observation for a year, during which time there had been little progress in the main features of the case. The knee-jerks were absent, station was swaying, sharp shooting pains were present in the legs, principally the right leg, with dull pain in the back, impaired muscular sense, slowness of micturition, Argyll-Robertson pupils, and some optic atrophy. There had never been crises or trophic disturbances, or girdle-sensation, or anesthesia. The hemianopsia had been noticed for about a year. It was thought to have come on suddenly, but there was no accompaniment in the way of headache, faintness, loss of consciousness, or other disagreeable symptoms. The left visual field was limited to the upper nasal quadrant; the right to the upper temporal quadrant.

THERAPEUTIC NOTES.

Iodoform for Fibrinous Rhinitis.—Vladar (*Pest. med.-chir. Presse*, No. 16; *Wiener medizin. Presse*, No. 23, 1894, p. 899) has found iodoform to be an excellent remedy—a specific he believes—in the treatment of fibrinous rhinitis. After irrigating the nasal passages, powdered iodoform is insufflated, the patient inspiring deeply. Sometimes cocain is additionally necessary to relieve the irritability and the sense of tension and fulness. It is well to have the patient breathe through a mask of gauze, for the useful effect upon the moisture of the cavities and upon the relaxation of the mucous membrane.

For Bronchitic Asthma.—

℞.—Ext. stramonii . . . . gr. ⅛.
Potassii iodid. . . . . gr. v.
Ammonii carb. . . . . gr. iv.
Tinct. lobeliæ æther. . . . ♏v.
Aquæ chloroformi . . ad ʒss.—M.

S.—A tablespoonful every four hours.

SATURDAY, JULY 28, 1894.

THE NEW ASYLUM AT WERNERSVILLE.

ON the 14th instant an informal transfer of the buildings of the new Asylum for the Chronic Insane at Wernersville was effected. The Building-Commissioners, who have about completed their task, resigned the charge of the new and extensive buildings to the Board of Trustees, who henceforth will have the care of the institution. This, practically, inaugurates not only a new *régime* at Wernersville, but also a new era in the history of the chronic insane in this State.

The subject is one of more than passing interest, and therefore deserves brief notice. We shall not attempt either to dictate a policy or to prophesy results; but, in common with many others, we have some opinions, hopes, and fears on the subject of the new hospital, which in moderation may be expressed.

The opportunity is now given, for the first time practically in this State, for the proper trial on an extensive scale of an improved scheme for the benefit of the chronic insane. As we understand the plan, the chronic insane are no longer to be merely incarcerated until they die; to be regarded merely as unfortunate, and, unfortunately, wards of the State; to be kept out of sight with a minimum of scandal and expense. On the contrary, they are to be a part, and an essential, integrant part of a great institution, sharing in its daily life, as far as in them lies, as a vital working factor. While they incur the usual isolation from the great social life of the outside world, which their condition demands and imposes, they are to be ushered into a social sphere where all at least is not blank; where interests may be awakened, where labor may yield its best rewards in some share of mental and bodily health, and where the instincts both of home and of nature may have an incentive and a partial realization. This is a noble ideal, and we doubt not a perfectly practicable one. The bane of our asylums is the torpor which they unconsciously and unintentionally impose. How often do we see the chronic lunatic killing time with hugging his delusions; how often the poor epileptic sitting vacantly waiting for the next fit!

The new asylum at Wernersville is exceptionally well located for the humane project of giving the chronic insane both a field of action and a home. In one of the most superb pastoral valleys of Pennsylvania, surrounded with not lofty but picturesque spurs of the South Mountains and Blue Ridge, it is fixed upon a fertile soil and in a climate of health-giving qualities. On the neighboring hills are a group of sanitariums which for years have demonstrated to the public the wholesomeness of this locality, while on the surrounding plain is an agricultural wealth which has always been the pride of the State. It is not easy to see how the natural advantages of the place could be surpassed, or how the authorities could have acted more wisely in selecting a site. The trustees will have under their care a large tract of farm-land, which will contribute its share to the support and health of the community.

The internal administration at Wernersville, and its results, will be watched with much interest. The design is to exempt as much as possible the physician in charge from the burden of administrative details; but with this there is no design to curtail his legitimate authority. This plan is in line with advanced thought on the subject of the internal administration of asylums. As we all well know, it is still subject to fierce criticism, and by none so fierce as by the asylum-superintendents, who suffer the most, and proclaim their sufferings the loudest, from the present infliction of housekeeping duties. This is one of the paradoxes, or anomalies, of present asylum-politics, and it is one

which, for better or worse, the trustees at Wernersville have faced squarely. The one disadvantage that their otherwise admirable site imposes, is, perhaps, its remoteness from large centers of scientific and medical activity. But this is not insuperable. The trustees have started with a good staff, who need have no difficulty, if they honestly desire, even in the rural depths of Berks County, in keeping up with the times.

We have been surprised sometimes to hear it said that the chronic insane do not offer subjects for fruitful scientific investigation: as if only the acutely insane are the legitimate objects of study for the pathologist. We protest earnestly against this erroneous thought. We beg to remind the reader that CHARCOT established at once his fame and the modern science of neurology on the studies that he made on the neglected old women in a Paris almshouse. Of the acutely insane few die, and the friends of fewer still grant autopsies. The morbid anatomist finds his best field in such an institution as that at Wernersville. We hope that it will not be said of it as of a similar hospital in another State, that it has no pathologist and that not ten per cent. of the fatal cases are examined *post mortem*. Let us trust that good clinical and pathologic methods will prevail, as well as good housekeeping.

We understand that a formal opening of the Wernersville Asylum will be held in the autumn. If so, we hope that it will cause to dawn then upon the profession and the public what an admirable institution of the kind we have in Pennsylvania.

THE TRANSMISSION OF TUBERCULOSIS THROUGH INFECTED MILK AND MEAT.

THE communication of tuberculosis by the flesh and milk of tuberculous animals has been sufficiently demonstrated to justify and demand the employment of stringent measures to lessen the possibility of such propagation of the disease. The unexpected discovery of tuberculosis in a herd of apparently healthy and well-nourished milch-cattle is not an infrequent occurrence, and a sufficient number of observations have already accumulated to demonstrate the utility and value of tuberculin as a diagnostic agent. It is fair to presume that if the same rigid measures of inspection and the same precision in diagnosis as have been employed in these isolated cases were extended to all cattle in the State, the results would exhibit a far greater prevalence of the disease than has ever been suspected.

At present, except in a very limited number of States, the consumer has no guarantee that such standard articles of food as meat and milk are free from disease-producing germs, simply because of the absence of well-digested laws regulating the preparation and sale of these commodities. Milk-inspection, as ordinarily practised in our towns and cities, valuable as it may be in detecting adulteration, is useless in protecting the public against the danger arising from those subtle pathogenic organisms which are at times conveyed by milk. In order to meet and subvert this danger new agencies must be invoked.

Inspection by the State—frequent, intelligent, and rigid—should be extended to the dairy-farm itself, and should embrace not only the thorough investigation of the cattle, but also an inquiry into their care and environment, so that in the course of time tuberculous disease may be completely eradicated and its re-introduction carefully guarded against. Provision should be made, by adequate laws, for establishing such inspection at the very source of danger, as a safeguard not only against tuberculosis, but against all diseases of an infectious type.

The enactment of such laws is always attended with difficulty, on account of the combination of adverse interests, and this opposition is predicated upon the assumption that vested rights are to be interfered with and pecuniary losses imposed by arbitrary administration of the law. Such opposition is to be overcome by making the laws judicious and mutually protective by not only guarding the public health, but also by protecting the interests of the dairyman as well.

The question of indemnification for loss sustained by the destruction of cattle has always been a stumblingblock in the way of this particular legislation. It seems fair and equitable that provision should be made for such reparation. The benefits are universal, and the loss should therefore be shared by the community.

It may possibly be remembered that at the last session of the Pennsylvania State Legislature an earnest effort was made to secure legislation on this important subject, but without avail. The necessity for legislation was admitted, but through the contentions as to the form, the bill failed to secure the necessary support.

Something more is necessary to secure protective

laws than a clear and conclusive argument before our legislators. Public opinion must be molded to a comprehension of the need of measures for guarding the public health, so that the men in our legislative councils shall be obliged to give the necessary relief. A weighty responsibility rests upon the medical profession in educating the masses in the right way of thinking on this subject. To the members of the profession is offered the opportunity for advancing knowledge, and they were derelict in their duty did they neglect an obligation which they owe to their fellow-citizens.

REVIEWS.

Clinical Gynecology: Being a Handbook of Diseases Peculiar to Women. By Thomas More Madden, M.D., F.R.C.S. Ed., Obstetric Physician and Gynecologist, Mater Misericordiæ Hospital, Dublin, etc. Philadelphia: J. B. Lippincott Co., 1893.

The able and conscientious work of this distinguished surgeon and writer throughout a period of many years has justly won for him the respect and admiration of his confrères in the domain of female pelvic and abdominal disease. The volume which he now offers to the medical profession is presumably the offspring of his varied experience, and as such has been seized upon assiduously by the gynecologists who have hoped to profit by the fruits of a busy and successful life spent in active clinical work. In noting the radical changes that have taken place in the methods of gynecologic treatment during the past quarter of a century, Dr. Madden pays a graceful tribute to the American surgeons who, he claims, have surpassed all others in their contributions to progressive gynecology. In many respects, the author in his management of the various pathologic conditions has kept pace with the advanced spirit of the times. Electricity as a gynecologic curative agent has failed in his hands—in this he is in accord with the other leading abdominal surgeons of the world. He recognizes the valuable assistance rendered by ichthyol in pelvic and vaginal disorders, and recommends it as one of the main aids in gynecologic therapeusis. While many such features as these, scattered throughout the volume, render the reading interesting and instructive, there are some startling deviations from the recognized practices of the day, together with omissions of matters of vital importance. Tuberculous endometritis is not mentioned at all, and tuberculous salpingitis, although as shown by statistics (*Johns Hopkins Hospital Reports*) it is present in 8 per cent. of all appendages removed, is merely mentioned as one of the possible varieties of chronic disease of the tubes. The treatment of ovariotomy is notably antiquated. The author adheres to the primitive method of cauterization of the pedicle with the thermo-cautery; in closing the abdominal wound he employs silver-wire sutures, which are now abandoned in favor of silkworm-gut by the vast majority of leading operators; unless there be a spontaneous action, the bowels are not opened until the tenth day, nor are the sutures removed until the same day, the patient thus being exposed to temperature-elevations and to the development of suture-abscesses. In reparation of perineal lacerations, Tait's operation is preferred, notwithstanding the acknowledged superiority of Emmet's method. As an anesthetic, the dangerous and uncertain A. C. E. mixture is recommended. Such failings as these mar a book otherwise acceptable and strong. The work of the publishers has been well done, and the illustrations and diagrams are numerous and valuable.

The Essentials of Chemical Physiology: For the Use of Students. By W. D. Halliburton, M.D., F.R.S., Fellow of the Royal College of Physicians, etc. 8vo, pp. xl, 160, and index. London: Longmans, Green & Co.

Dr. Halliburton is well known to the profession by his contributions to current literature and to students by his comprehensive *Text-book of Chemical Physiology and Pathology*. The present work is not a mere condensation of the larger, but is intended as a guide in the practical study of physiologic chemistry, while giving also brief summaries of the existing knowledge. It is excellently printed and largely illustrated with well-executed cuts.

The text represents, of course, the accepted views on the many complex topics in this department of science. It is to be regretted that writers and teachers of physiology are so frequently indifferent to accuracy in expression of chemic terms. In using the terminology of any biologic science, the physiologist would certainly seek to conform to standards accepted by the authorities, yet in the chemic nomenclature a looseness prevails which is exasperating. The phraseology of the present-day chemistry is fairly exact and systematic, and an effort should be made by all writers to adhere to its principles. We are moved to these remarks by noticing on page 16, the now antiquated and absurd statement that the fats are compounds of fatty acids with glycerin. Under glycerin, the alternative and now approved name, glycerol, is given, but is not again used. So also, such terms as "potassium hydrate," "phosphate of lime," are unwise. The use of such phrases in a text-book like this one interferes with the satisfactory work in the chemistry department of a college. The authority of the distinguished author is such that a student may feel justified in using erroneous or antiquated phrases because he finds them in good company. It is pleasing, however, to note that these defects are not frequent, and that generally the nomenclature is correct and the composition of all important bodies correctly given. The detailed statement of the composition of the urine is a decided improvement upon the confused tables often given, but it would be still more satisfactory if the exact molecules indicated by the terms sulfuric and phosforic acid were indicated. The work is certainly a useful addition to our text-book resources.

Venereal Memoranda. A Manual for the Student and Practitioner. By P. A. Morrow, A.M., M.D., etc. 12mo, pp. 332. New York: William Wood & Co., 1894.

We are told that the aim of this somewhat oddly-named volume is to give a concise exposition of the

nature and treatment of venereal diseases. We are also told that "in the effort to condense so much important material within necessarily narrow limits the sententious style of expression adopted naturally assumed the form of aphorisms." But the aphoristic feature seems to consist merely in the arrangement of the matter in short paragraphs. It is surely not sententious—we doubt if it is correct—to say: "A leukorrhea which would have remained innocuous after a single coitus takes on irritatant properties under the influence of repeated intercourse, developing a potentiality for mischief which it did not before possess;" or, "The man who exposes himself to a possible source of contagion should not linger long in the lap of Venus. 'Cito tuto et, etc.,' is a safe motto."

Again, we are told in the preface to this second edition, for such it purports to be, that "full recognition has been given to modern microbian (*sic*) theories in connection with the etiology of these diseases;" yet we look in vain for any hint or trace of allusion in the text to such theories.

We do not think this book will benefit any class of readers, or add to its author's reputation.

Syllabus of Lectures on the Practice of Surgery. Arranged in Conformity with the American Text-book of Surgery. By N. Senn, M.D., Ph.D., LL.D., Chicago, Professor of the Practice of Surgery and Clinical Surgery in Rush Medical College, etc. Small 8vo, pp. 221. Philadelphia: W. B. Saunders, 1893.

The distinguished author of this little work may be allowed to state its purpose in his own words: "Every teacher of surgery must have felt the need of some short guide to aid him in the lecture-room in presenting the various subjects in a systematic, clear, succinct, and practical manner. The student of surgery during his early college experience is often bewildered by what he hears and reads, and keenly experiences that want of something which should enable him to separate the chaff from the wheat, and to memorize facts which he is expected to retain and apply at the bedside during his future professional career. This little book has been written to meet these requirements."

We must confess that we do not think any professor of surgery of our acquaintance would use this book as a "short guide" in the lecture-room, although it might answer, like the table of contents in a text-book, as an aid in the arrangement of his material. Nor can we see how it can help the bewilderment of the student. He ought not to have any chaff given him; and it seems to us that his facts will be of more use to him if they are in his mind as parts of a systematic and philosophic whole, than if they are "memorized." The true value of such a book as this, and we do not rate it highly, is as a convenient table of subjects to be studied and an exhibit of their main points. As a source of information it is too terse and fragmentary to be of any avail to the tyro, while the experienced and well-informed do not need it.

Our comment is upon the avowed purpose of Prof. Senn's book. His intelligence and learning qualify him for any surgical task, and he has done this one well. But we think it hardly worth the doing.

CORRESPONDENCE.

POTASSIUM PERMANGANATE IN OPIUM-POISONING.

To the Editor of The Medical News,

Sir: At this time, when so much interest is felt in the recent commendation of potassium permanganate as an antidote to the poisonous effects of opium, every personal experience in this connection should prove of interest.

On June 11th, about 10 P.M., I was summoned to see Mr. R., who had taken about a half-hour previously two ounces of laudanum. Upon my arrival I found him unconscious, and breathing with difficulty, with the typical pin-hole contraction of the pupils. I immediately wrote a prescription for a solution of potassium permanganate, of the strength of six grains to the ounce, and despatched a messenger with it to the nearest drug-store a few blocks away. I then gave a hypodermatic injection of apomorphin hydrochlorate, gr. $\frac{1}{10}$, and thus thoroughly emptied the stomach of that portion of the drug that had not been absorbed, and directed that some strong coffee be prepared at once. I gave atropin sulph. gr. $\frac{1}{100}$ hypodermatically, at intervals of fifteen minutes, until three doses were taken, emptied the bladder with a catheter to prevent reabsorption, also using wet towels by flagellation over the chest to stimulate respiration. All efforts at resuscitation seemed futile; the pulse, at first full and bounding, became weaker, the breathing exceedingly difficult and labored, with the intervals between the respirations rapidly lengthening and the pupils gradually dilating, until at 11 P.M., when the permanganate-solution was handed me I had been for more than fifteen minutes able to detect scarcely any pulse-beat, and the respiration was little more than an occasional gasp. The delay in procuring the solution was due to the fact that the drug-clerk had to be awakened, and after a search for the desired article failed to find it, having only just gotten his stock moved in from another building. This necessitated going several blocks further on, and rousing a second clerk to have the prescription compounded, so that it was quite an hour from the time I arrived, and an hour and thirty minutes from the time the laudanum was taken, before the permanganate-solution could be used. I immediately injected into the patient's arm twenty-five minims, and succeeded in getting him to swallow probably a teaspoonful. Within a few minutes the respiration was somewhat improved, and I was able to detect a faint beating of the pulse. I repeated the injection, which was followed by still further improvement in the symptoms. The hypodermatic injection of the solution was then continued at intervals of fifteen minutes until seven were given, three in the right arm, two in the left, two over the region of the heart. The patient was walked more or less constantly. After each injection decided improvement was noted, so that whereas at 11 P.M. he was in a state of profound coma, at 1 A.M., or two hours thereafter, and three and a half hours from the time of taking the laudanum, which was equivalent to sixty-four grains of the crude opium, and sixteen of its principal alkaloid, morphin, the patient was seated on the veranda conversing quite intelligently with me and the members

of his family. I then deemed it quite safe for him to retire for the night, but placed a close watch over him. During the succeeding day he remained in bed, but on the following morning he was at his office as usual. I think I can safely say that but for the timely arrival of the permanganate-solution he would undoubtedly have been dead within fifteen or twenty minutes. I may also add that for several days there was considerable inflammation at the site of each puncture, and I directed that flaxseed-poultices be applied, and be permitted to remain over night, whereupon it promptly disappeared.

Respectfully,

C. EVANS JOHNSON.

ATLANTA, GA.

UNPROFESSIONAL CONDUCT, OR IMPOSITION?

DR. JOHN C. SUNDBERG, U. S. Consul at Bagdad, sends us an advertisement of "animal extracts," taken from a New York daily newspaper, and expresses wonder whether the physician, according to whose formula the "extracts" are prepared, is guilty of unprofessional conduct or the "chemical company" by which they are manufactured, of unauthorized use of the physician's name. "Cardin," he goes on to say, "is of Eastern origin, children's hearts being considered specific in the treatment of heart-disease and carcinoma, and an hereditary Bagdad saint, with a saintly pedigree dating back eight centuries, is reputed to have agents constantly in the field to capture children, that he may eat their hearts. It is highly probable that the Babylonian fakirs gave their illustrious American confrère the first idea of the therapeutic value of heart-extract and other such preparations."

SOCIETY PROCEEDINGS.

AMERICAN ORTHOPEDIC ASSOCIATION.

Eighth Annual Meeting, held at Washington, D.C., May 29, 30, 31, and June 1, 1894.

FIRST DAY—MAY 29TH.

DR. ROYAL WHITMAN, of New York, read a paper entitled "Observations on Bending of the Femur in Adolescents." This condition, he said, developed in adolescents who had grown very rapidly, or who had been subjected to overwork or strain. In 1889 E. Müller had reported, as a new type of disease, four cases of bending of the neck of the femur. During the past two years four such cases had come under Dr. Whitman's observation, two of which he reported. The first of these cases was in a boy, who for a year, without known cause, presented a gradually increasing limp, and for six months had found it necessary to use a cork sole. The appearance was that of congenital dislocation of the hip. The actual shortening was three-fourths of an inch, and the apparent shortening was three and a half inches. There was no limitation of flexion, extension, or rotation of the limb. The movements were free and painless. The head of the bone was in the acetabulum. In the second case the diagnosis had been made at an earlier stage. The patient was a boy of sixteen years, in whom there was a bending of both femoral necks. At the time he came under observation there was nothing of special importance, except for slight eversion of the feet and flat-foot. There was slight knock-knee; the trochanters were a little above Nélaton's line; the gait was somewhat rolling in character, and abduction was about one-third of the normal. Rest and gymnastic exercises were advised, but were not carried out. The boy appeared three months later, with a much worse gait. Behind each trochanter was a deep sulcus; the legs were adducted, and on attempting to flex them they were immediately crossed one upon the other. There was no pain or spasm. In the course of ten months adduction had increased, so that it was only with the greatest effort that the legs could be passed by one another. It was believed that the bending of the neck had nearly reached its limit, and it was therefore proposed during the summer to divide the leg below the trochanter. In all the cases flexion of the thigh has caused the trochanter to be more prominent.

The bending appears to be a comparatively rapid process, and the head of the bone is usually depressed downward and backward in the line of least resistance. When the condition is one-sided, the symptoms are stiffness and limp due to shortening; if both sides are affected, adduction of the leg causes a peculiar, rolling gait, due to the interference of the knees. The character of the pain is similar to that seen in knock-knee and the bow-legs of adolescents. The treatment consists in (1) removing the exciting cause, which is usually overwork or some special occupation causing strain on the parts; (2) local massage, manipulations, and passive motion in the direction of the restricted motion; (3) osteotomy below the trochanter. In the stage in which these patients usually presented themselves, the diagnosis offered no particular difficulty. In all cases of dislocation upward, the neck of the displaced bone could be traced upward and the head of the femur made out; in bending of the femur only the prominent trochanter could be felt. If the distortion were due to necrosis or other chronic disease, the evidence of such disease would be apparent. There was no local swelling or infiltration, and the abduction and inward rotation were the only motions which were limited. When unchecked the deformity showed a marked tendency to increase upward.

DR. WALLACE BLANCHARD, of Chicago, then exhibited his hip-splint, which he said he had used with satisfaction for twenty-two years. Longitudinal traction was made by adhesive straps, and lateral traction by a band around the thigh. The main strip extending down the back of the thigh and leg secured the very necessary immobilization. The splint should be molded to the body and limbs, and should not cause pain. It was both a bed-splint and a walking-splint, and should not be removed except for repairs. From eight to nine pounds of traction were usually sufficient for children—although fifteen or twenty pounds might be necessary for the first day or two.

DR. A. M. PHELPS, of New York, discussed "The Question of Priority in the Application of Lateral Traction to relieve Intra-articular Pressure in Hip-joint Disease." His first paper on this subject had been published in the *Medical Record*, May 4, 1889, and in August of the same year, Dr. Blanchard had published a paper in which he stated that he had been using lateral traction. Sayre claimed to have applied lateral

traction to a patient in 1872, but, as a matter of fact, the straps were applied to overcome the inward rotation. The Germans had mentioned lateral traction in 1873, but only as an argument against the usual form of traction, as they did not believe in traction at all.

In the discussion on the foregoing, DR. A. M. PHELPS said that the chief objection to Blanchard's splint was the fact that it did not extend below the bottom of the foot.

DR. BENJAMIN LEE, of Philadelphia, remarked that in the hip-splint used by Dr. Taylor and himself in 1862, he thought lateral traction was made.

DR. WHITMAN said that while he believed the principle of lateral traction was good, the mode of its application in Dr. Phelps' apparatus seemed very inefficient.

DR. PHELPS said that if the splint were bent away far enough from the thigh, and the traction were applied just above the knee-joint, it would prove effectual in relieving intra-articular pressure.

DR. L. A. WEIGEL, of Rochester, reported two cases of congenital dislocation of the hip. The first was in a boy who had been delivered after a difficult labor resulting from a foot-presentation. There were a number of convulsions during the first three or four days of life. An abnormal condition of the hand was noticed soon afterward, but the disability of the leg was not observed for a considerable time. The child was inclined to be vicious and destructive. There was a marked spastic condition of the left arm and it was shorter than its fellow. The head of the femur was freely movable on the dorsum of the ilium, and with slight traction and rotation the head could be drawn down to its normal position. It easily returned to the former position. The existence of a rudimentary acetabulum could not be determined. The ophthalmoscope showed double optic neuritis and secondary atrophy from some intra-cranial cause. The long traction-splint was applied for the purpose of maintaining the limb in proper position and enabling the child to walk. Massage was ordered for the arm. A recent examination had shown remarkable improvement. Three weeks ago the boy had begun to stand, and was now walking; the hand could not be opened voluntarily. On removal of the splint, however, the hip returned to its former abnormal position just as readily as before. The mental condition was decidedly improved. In the second case the child had been noticed shortly after a normal delivery to have an abnormality of the right hand, and on beginning to walk, a "hip-limp" was detected. There was a well-marked spastic condition of the arm and leg, and a displacement of the right hip. The dislocation of the hip was readily reduced. The acetabulum was but slightly developed. The mental development of the child was normal. There was no history of instrumental labor, premature birth, or asphyxiation, yet the tonic contraction of the arm was greater than in the first case.

DR. BENJAMIN LEE referred to a case first seen about sixteen years ago, and presenting a spastic condition of the left arm. When seen again quite recently, all of the movements of the hip were somewhat restricted.

DR. F. S. COOLIDGE, of Chicago, suggested that Dr. Weigel's case might have had a dislocation resulting from severe spastic contraction of the foot from disease of the brain.

DR. WEIGEL replied that the spastic condition had existed before birth.

DR. A. E. HOADLEY, of Chicago, read a paper on "The Etiology of Deformities in Knee-joint Disease." His paper was intended as an answer to one read by Dr. Phelps at the last meeting of the Association. He said that anatomy taught that the knee-joint was not a simple hinge-joint, inasmuch as there was no common center around which the head of the tibia revolved. Again, as the condyles were of unequal length, there was a rotation of the tibia upon itself, thus making the knee-joint a very complicated joint. The flexors and extensors were equally balanced in a fully extended limb, but as flexion progressed, the flexors were diminished in power because the tendon of the quadriceps constantly changed its direction until it reached 135°, when the flexors actually became extensors. Thus, a leverage of one and a half inches was gradually diminished to no leverage at all at 135°. Beyond this point it was impossible for flexion to occur voluntarily. Measurements in a number of students showed that with the leg straight, the power of flexion was about seventy-five pounds; when lying down on the back with the leg flexed at right angles and the knee pressing against a block the power of flexion was only about forty pounds; while with the leg at 90° the power of extension was about one hundred and seventy-five pounds. The strongest point of the flexors was weaker than the weakest point of the extensors, and between 90° and 130° there was no appreciable difference in the power of the extensors. In conclusion it was said that the preponderance of power was in favor of the extensors; it had nothing to do with producing the deformity of the limb. Nor was it thought that there was anything in the clinical history to show that the extensor muscles atrophied any faster than the flexors.

DR. W. E. WIRT, of Cleveland, Ohio, gave a mathematic demonstration of the method of determining the amount of force and of the amount of friction.

DR. WHITMAN thought that one important factor—the gastrocnemius muscles—had been left out of consideration.

DR. A. M. PHELPS said he believed the propositions in the paper were incorrect. The results which he had himself obtained by experiment tallied very closely with those of Horton, of Dublin, and represented a force of about thirty-five pounds, while Dr. Hoadley had estimated the force at seventy-five pounds. The same might be said about the other figures. It should not be forgotten that when the leg was flexed the quadriceps muscle acted over a pulley, and its force was necessarily diminished by friction. When in the straight position there was no friction, but when flexed, there was a force so great that it might even cause fracture of the patella. In his own experiments he had found that when the leg was perfectly straight the extensors were at the greatest possible advantage, and that the amount of resistance was two hundred and forty pounds, as against one hundred and thirty-six pounds when the limb was flexed. Again, owing to the insertion of the muscles, they were acting on a lever represented by the distance from the attachment of the muscle to the center of the bone. As the limb was flexed the lateral ligaments were relaxed, and the biceps tendon, being at-

tached to one side of the end of the fibula, was really attached to a lever, having a length equal to the distance from the center of the condyle to this attachment of the muscle. This necessarily rotated the limb outward. His conclusions were that the typical deformity was produced by a voluntary effort to prevent pain by relieving intra-articular pressure.

Dr. John Ridlon, of Chicago, pointed out that no account had been taken of the fact that as a muscle approached its point of full contraction its power diminished.

Dr. Hoadley said that he had considered this point in a portion of the paper which he had omitted in reading. The friction produced by the tendon passing over the pulley was so slight that it could be neglected. Dr. Phelps' experiments had been confined to only one man, whereas his had been made on eighty students.

Dr. E. H. Bradford, of Boston, made some remarks in connection with the presentation of a pathologic specimen from a case of Hoffa's operation for congenital dislocation of the hip. The object of this operation was to make a new acetabulum for the reception of the head of the femur, and Hoffa claimed that as the acetabulum was always the thickest portion of the bone, there was no danger of perforation in curetting out this new acetabulum. That this claim was incorrect was shown in the specimen. It also showed that, although it was not detected on palpation during the operation, the original acetabulum was well developed. Attention was also called to the fact that when the head of the bone was placed in the acetabulum the limb could not be straightened, apparently because of the obstacle offered by the Bigelow Y-ligament. It was, therefore, suggested that the capsule be divided anteriorly. The belief was expressed that if these cases were carefully operated upon, the condition would prove to be a curable one.

Dr. Bradford also presented a specimen of rachitic deformity of the hip in an adult, and a knee-joint showing a periostitis just above the head of the tibia.

Dr. Whitman said that Lorenz's operation was practically the same as the modified operation suggested by Dr. Bradford. He approved of this operation, and agreed with Dr. Bradford as to the obstacles to reduction. He emphasized a point that he believed was not generally fully appreciated, viz., that there was great disability, and often pain or discomfort in these cases of congenital dislocation of the hip.

Dr. Weigel admitted the great amount of disability present in cases of double congenital dislocation. In his cases there had been no difficulty in reducing the deformity. As he believed that in all cases the acetabulum was not rudimentary to the same degree, he thought some cases might be relieved by continued contraction.

Dr. De Forest Willard, of Philadelphia, said that he thought the acetabulum was more seriously deformed in most cases than it was in the specimen that had been presented. When there was a long, oval-shaped acetabulum he did not believe operation was likely to be successful. He had seen great disability, but never true pain.

Dr. Bernard Bartow, of Buffalo, reported the case of a child, three years old, in whom the use of traction continuously for a period of about six months resulted in maintaining the head of the bone in its proper position, so that it would not be dislocated by the application of a reasonable degree of force. This would seem to prove that the acetabulum was fairly developed in some of these cases.

Dr. Wirt said he had seen cases of this kind in which there had been actual pain on walking.

Dr. Phelps said that as not a single case of congenital dislocation had been cured by mechanical treatment, and a cure had been effected by Hoffa's operation, this operative treatment was the only method worthy of trial. If suppuration occurred, there would be reflex spasm, and this would result in serious deformity.

Dr. Bradford said that, judging from an examination he had made of three other dried specimens in the Warren Museum, there was a ridge of bone at the upper and posterior edge of the acetabulum in older subjects, but in children the condition seemed not to be due to an arrest of development, but to genuine *congenital* dislocation. Suppuration following Hoffa's operation was a serious complication. While admitting the great value of operative treatment, Dr. Bradford still felt that as there was not much disability in some adult cases, mechanical treatment should be tried when it held out any prospect of success.

Second Day—May 30th.

Dr. C. G. Page, of Boston, by invitation, read a paper on "Lateral Traction in Hip disease." He said that lateral traction alone did not seem sufficient to give relief. The object of traction was to overcome spasm and "distract" the joint, if possible; and to do this, the head of the bone must move practically in the axis of the neck. Such a force was not at our command, but the resultant of two forces enabled us to accomplish this in practice. The point of application of the lateral force was necessarily considerably below the head of the femur. It had been objected that lateral traction when applied high up shortened the muscles and tended to draw the bone toward the acetabulum; but it should be remembered that the muscles became lengthened and adapted to the new condition. About five pounds of lateral traction should be used to ten pounds of longitudinal traction, and it should be applied at 15°.

Dr. Phelps said he was prepared to indorse nearly all the conclusions announced, but he thought the proportion between the two forces should be about two of lateral to eight of longitudinal traction.

Dr. V. P. Gibney, of New York, read a paper entitled "Final Results in One Hundred Cases of Operation for Deformities following Hip joint Disease." He suggested that it might possibly be better while the disease was still active to give less attention to simple efforts at aiding Nature in protecting the joint, and more attention to the operative correction of the deformities resulting from the disease. As a rule, the long traction-splint prevented exacerbations, and gave the patient comparative comfort. He had had an opportunity to observe for a period of a dozen years the sufferings of those in whom hip-joint disease was allowed to run its natural course, and he had also had an opportunity to observe for a similar period the results of the use of portative apparatus, so that he felt he could hardly be accused of presenting the subject from only one point of view. He reported several illustrative cases, and presented in carefully

tabulated form the results of his operations, and of the treatment with splints and with the weight and pulley.

Dr. Wirt said he had witnessed some of the operations done on these cases, and had followed them for for some time afterward. He thought the method of treatment by osteotomy exceedingly useful; it had certainly given him good results.

Dr. S. Ketch, of New York, thought Dr. Gibney's results indicated that the use of force in the reduction of the deformity was a dangerous practice. In his opinion, it was a plan of treatment that should be abandoned.

Dr. Whitman said that Dr. Gibney seemed to be wavering in his belief as to whether it was profitable to prevent these deformities, as it was so easy to correct them afterward. Surely Dr. Gibney was familiar with many neglected cases in which there had been adduction, flexion, and upward dislocation. The latter condition could not be corrected by any operation. He felt sure that the remarks made bad been directed chiefly against the dispensary class of cases.

Dr. Ansel G. Cook, of Hartford, detailed two cases in which he had obtained gratifying results from this method of performing osteotomy.

Dr. Gillett asked if Dr. Gibney would operate for the relief of the deformity in cases in which there were discharging sinuses.

Dr. Gibney said he would wait for the sinuses to close, and would hasten this process by curetting them. For some time past he had been of the opinion that in some cases in which there were acute symptoms, and deformity already existed, it was best not to forcibly correct the deformity, for this was liable to cause the formation of an abscess in some inaccessible part. In many cases of deep femoral abscess in which it was practically impossible to properly cleanse the abscess-cavities, he thought it wise to let them alone until the disease had exhausted itself. He wished to place himself on record as unalterably opposed to allowing deformity to develop in any stage of the disease; but when changes had occurred in the shaft and neck of the femur as a result of the exanthemata, before the cases came under observation and when there was probably fusion of the neck and head with the acetabulum, he preferred to let the disease run its course. He did not agree with Dr. Ketch that the method of forcible correction should be abandoned. There were many cases with acute symptoms in which no splint could be applied until the deformity had been corrected, and in which traction in bed could only be made upward toward the ceiling. His experience had taught him that after the correction of the deformity, particularly after osteotomy, a short Thomas splint should be worn for some time after the operation.

Dr. Phelps said that in nearly all cases the deformity could be overcome by rest in bed and the use of a weight and pulley.

Dr. Herman Mynter, of Buffalo, read by invitation a paper on "Excision of the Wrist by a New Method." He said excision was usually resorted to only in old, neglected cases, in which it was only possible to remove the fattily degenerated and softened bones piecemeal, thus leaving much tuberculous matter in the wound. He asked what would be the result if the knee-joint, or any other joint, were exsected in such a way. Professor Stuttgar, of Copenhagen, had advocated a new method of making the incision, with the object of gaining better access to the metacarpus. It includes a supplementary incision made longitudinally between the third and fourth metacarpal bones. The superficial and deep palmar arches must, of course, be ligated. Dr. Mynter had found it unnecessary on the palmar side to extend the incision further than the base of the thenar. The whole carpus could be widely opened, and it was extremely easy to excise it in two portions. The cavity was packed with iodoform-gauze, and the wound in his case healed by first intention, except where the gauze was brought out. Eight weeks after the operation the woman was able to extend and flex the wrist and move the fingers.

Dr. F. S. Coolidge, of Chicago, made some remarks on "Osteoclasis," and demonstrated the action of the Lorenz osteoclast. He said that Lorenz had been using this instrument for six years, and had attained most excellent results. The instrument was used for the correction of deformities of the leg. It consisted of two plates, the one movable and the other fixed. The long handles gave tremendous leverage, but the screw-thread was so fine that it admitted of perfect control. The plates were placed at such an angle that in the performance of osteoclasis they would usually be at right angles to the bone at the moment of fracture. With this instrument osteoclasis rivalled osteotomy in its exactness. It fractured the bone in the desired direction, away from the deformity, and within a fraction of an inch of the selected point. The fracture was generally sub-periosteal. With this instrument knock-knee could be even over-corrected at one sitting, without rupture of the ligaments of the knee. A knock-knee brace should be worn constantly for one year afterward, at which time a cure would have been effected. The pain after the operation lasted usually only about twenty-four hours. This method corrected the deformity as rapidly as osteotomy, and without its dangers, slight though they were.

Dr. Halsted Myers, of New York, said that if it were necessary to wear a knock-knee brace for one year after the operation, the method possessed no advantage over purely mechanical treatment, for a cure could be effected with the latter in about the same time.

Dr. Phelps said that if the Rizzoli osteoclast were made sufficiently rigid, it would be found about the best instrument obtainable. Next to this came the Grattan osteoclast. He thought osteotomy should not be performed when osteoclasis could be done, but the latter was not suitable for producing fractures near a joint. From our knowledge of the pathology and etiology of genu valgum it was hardly to be supposed that the deformity could be removed by osteoclasis without either osteotomy or osteoclasis in the shaft of the bone.

Dr. Coolidge said he considered that the instrument accomplished its best work in the correction of the anterior and posterior flexions of the knee-joint.

Dr. Royal Whitman, of New York, opened the discussion on the subject of "Flat-foot." He said that Dr. Shaffer's theory was that flat-foot was caused by primary contraction of the tendo Achillis. Each individual muscle had been accused in turn of being the primary cause of this affection. In most of the theories that had been advanced, he thought effect had been mistaken for cause. Flat-foot was the result of the relative disproportion between the work to be performed and the

weight to be supported, and the weight of the supporting structures. It was most commonly brought about by habitual improper attitudes. Flat-foot was a dislocated foot, and hence the resistance of the tendo Achillis was often apparent rather than real. If flat-foot was to be cured, this dislocation must be reduced, and kept reduced. Finally, the balance of power must be regulated by treatment directed to the muscles, and the position assumed by the foot. Flat-foot, according to his experience, was an eminently curable affection, the age of the patient and the duration of the condition being important factors. He did not believe in cutting operations of any kind, as he had never seen a permanent or satisfactory result from them. These remarks were based on an experience with upward of one thousand cases of flat-foot.

Dr. Weigel said he had been much pleased with Dr. Whitman's method of treatment. He had simplified somewhat the preparation of the pattern by making it out of three layers of crinolin, applied to the foot in strips dipped in thick plaster-of-Paris cream. The plates were cast after this pattern, and were made of an alloy, the chief ingredient of which was phosphor-bronze.

Dr. Ansel G. Cook, of Hartford, said that if the old flat-foot springs were properly made they would meet every indication for treatment.

Dr. Whitman objected to these springs strongly, on the ground that they allowed a lateral broadening of the foot.

Dr. Cook replied that the lateral pressure was furnished by the patient's shoe.

Dr. A. Jacobi, of New York, by invitation, opened the discussion on "Rachitic Deformities." He spoke of the rapid increase of rickets in this country during the past thirty years as a result of unrestricted immigration, and said that in the future the treatment of this condition would be a social as well as a medical problem. He then gave a detailed and graphic description of the various lesions and deformities due to rickets. Referring to the head, he said that it was possible for craniotabes to entirely disappear if the rachitic condition which had produced it had not lasted for any great length of time. The frequent occurrence in rickety children of the so-called "Hutchinson teeth" had probably given rise to the belief that all rickets was the result of syphilis. Many cases of so-called "growing pains" were nothnig more than examples of rachitic epiphysitis. It should be remembered that in rickets the muscles suffer as well as the bones, and that both the voluntary and involuntary muscles may be involved. Rachitic pseudo-paralysis was not paralysis at all, but simply a weakness of the muscles. The heart was usually rather large, and the arteries small. The muscular coats of the stomach and intestine were involved, and hence constipation was an early and prominent symptom.

Dr. Benjamin Lee, of Philadelphia, in continuing the discussion on rachitis, spoke particularly of "Its Various Manifestations, Diagnosis, Differential Diagnosis, and Prognosis." He paid especial attention to rickets in its early stage. It was essentially a failure on the part of the system to assimilate the earthy salts, especially the salts of lime. It was a well-established fact that children might be born rachitic. It was not uncommon for the rachitic infant to appear well developed and robust during the first months of life, and, consequently, the true condition was often overlooked. Tetany and laryngismus stridulus were common symptoms. The utmost care should be observed to avoid confounding the early symptoms with those of simple bronchitis and gastro-enteric catarrh. Rickets, and its congener, scurvy of infancy, had been rapidly increasing recently, quite probably because of the extensive use of sterilized milk.

Dr. S. Ketch, of New York, spoke of "The Local, Mechanical, and Constitutional Treatment." He said that one of the most important means in preventing deformity was the avoidance of injurious positions in the early stages of rachitis. Especially was this true in the stage of tenderness. The portative frames were useful in carrying out the postural treatment. Cautious manual pressure made daily was an important measure; climatic and hygienic treatment should not be forgotten, and the medicinal treatment should be adapted to the individual case. The ease with which the bones could be sprung toward their normal position should be the measure of the force to be employed. It should not be painful, but should be kept up for a number of minutes. It should be a cardinal rule that as long as the bones were in the stage of softening mechanical treatment should be persistently followed.

Third Day—May 31st.

Dr. De Forest Willard, of Philadelphia, read a paper on "The Operative Treatment of Rachitic Deformities." He said that in manual correction of rachitic deformities, the pressure should be made momentarily and intelligently. He had never seen sloughing occur under these conditions. Straightening should take place before fracture, although "green-stick fracture" occasionally occurred. There was but little pain following the application of such force. In a number of instances in which he had compared forcible straightening and osteoclasis, he had found that the straightening was more pleasantly and more efficiently accomplished by forcible straightening, even in children of five or six years of age. Osteotomy, he considered the operation *par excellence* for rachitic deformities. He had seen suppuration occasionally follow the performance of cuneiform osteotomy, but in the other forms of osteotomy it had almost never occurred in his practice, and primary union was the rule. He preferred not to use an Esmarch bandage, for when there was a free flow of blood there was less likelihood of an inflow of air. It was true there was a slight mortality connected with osteotomy, yet he would like to see the statistics of the last few years, for he had observed no deaths and had heard of none. He did not believe a bone could be fractured with an osteoclast until all the soft tissues had been compressed and lacerated down to the periosteum; and, consequently, he considered osteotomy better than osteoclasis.

Dr. Weigel said that with ordinary care and supervision after the operation, he considered either linear or cuneiform osteotomy perfectly safe, and preferable to osteoclasis. He had entirely discarded drainage.

Dr. Ryan, of Cincinnati, thought the chief difference between osteoclasis and osteotomy was the difference between precision and uncertainty. He thought cunei-

form osteotomy had been practically abandoned except for the anterior curvatures of the tibia. He did not think osteotomy should be performed before the age of four or five years, as before this there was likely to be a recurrence of the deformity.

Dr. Gillette said he had never done osteoclasis, because he had always felt that it lacked precision. He then detailed his experience with a case of osteotomy which had been followed by non-union.

Dr. Cook said he had done a number of osteotomies, and had always sealed the wound. He had never seen any pus in any of these wounds.

Dr. Bartow, of Buffalo, said the fear of injuring the soft parts by osteoclasis appeared to him to be not well founded. With the osteoclast one could often make a green-stick fracture, and thus not only reduce the deformity, but obtain the benefit of the partial fixation offered by the bone itself.

Dr. W. R. Townsend, of New York, said he had seen one case in which Mr. Grattan had himself produced a laceration of the soft parts by the use of his osteoclast. As no special antiseptic precautions were taken in the preparation of the field of operation previous to doing osteoclasis, such slight lacerations might offer an entrance for septic germs.

Dr. Coolidge said that Lorenz had effectually obviated this difficulty by the use of pads of very thick rubber.

Dr. Bartow said that he had avoided such lacerations by applying a piece of moleskin plaster at the point where the pads and girdles of his Rizzoli instrument were to make pressure.

Dr. Ketch said he did not think any of these cases recovered without at least some simple manipulations. He would like to hear from the others about the "growing-out" theory.

Dr. Ryan replied by detailing the history of four boys in a family under his constant observation, in whom these deformities had disappeared as the children had grown up.

Dr. Willard said that he now seldom did cuneiform osteotomy, but when he did he left the wound open. When there was a very free effusion of blood it seemed that sufficient callus was not thrown out. This might explain the case of non-union reported by Dr. Gillette. Bad results were often due to the faulty application of dressings by inexperienced assistants. The most common mistake after osteotomy was in allowing the patients to go around without support. Some form of support should be worn for one year.

Dr. J. C. Schapps, of Brooklyn, read a paper entitled "Relief of the Spondylitic Spine from the Concussion of Walking." He said that to minimize the concussion of walking he had for about two years been using thick rubber heels, over half an inch thick. These should not be nailed, but stitched to the shoe.

Dr. Bernard Bartow, of Buffalo, read a paper on "Elastic Traction in the Immediate Treatment of Club-foot." His method of employing elastic traction was modelled after that of Mr. Barwell. His object was to supplement tenotomy by grasping the anterior part of the foot, and abducting and twisting it more nearly into its normal relations. Over-correction was secured by elastic bands attached by adhesive plaster at the base of the little toe, and by a second plaster attached at the knee, and near the outer margin of the patella. The varus element yielded particularly well to this method.

Dr. Newton M. Shaffer made some remarks on the value of intermittent traction in general, and particularly its beneficial influence on the nutrition of the parts.

Dr. W. E. Wirt, of Cleveland, O., read a paper entitled "Phelps' Method for the Cure of Club-foot in Adults." He reported three cases, ten, nineteen, and twelve years old, respectively, in which he had performed the operation of Phelps. He believed that tenotomy, the open incision and removal of the tarsal wedge, and sometimes the removal of the astragalus, would in most cases result in securing a useful foot. The skin in adults, and in some older children, would not stand the strain, and would slough.

Dr. Weigel reported a case of double club-foot and double club hand in which there was an extreme degree of deformity. In another case, that of a girl of twelve years, he had done Phelps' operation on one foot, and had removed the astragalus from the other foot. The latter gave a much better result. The trouble with Phelps' operation was that, with it, it was almost impossible to secure a complete correction of the varus.

Dr. W. R. Townsend said that the secret of Dr. Phelps' success in these severe cases was not in the open incision, but in the tremendous force which he used. The limitations of the operation were greater than had been supposed, for it was not indicated in very mild cases, and when there was retraction of the soft parts and extreme bony deformity, it was bound to fail.

Dr. Ketch said that in cases in which the bony distortion exceeded the contraction of the soft parts, Phelps' operation was not a success.

Dr. Coolidge, on behalf of Dr. Halsted Myers, of New York, described a new method of operating on these cases. When it was necessary to remove one of the bones of the foot, Dr. Myers advised making a small incision over the bone, and scooping out with a Volkmann's spoon all the spongy tissue in the interior of the bone. Then, with comparatively little force, the foot could be brought into position.

The discussion on flat-foot was then resumed. Dr. N. M. Shaffer, of New York, spoke of the mechanism of the production of flat-foot, and illustrated his remarks with a mechanical model. There was, he said, practically no motion at the foot, and the center of motion of the ankle-joint passed transversely through the astragalus at about the outer malleolus. Motion of the ankle-joint took place on a remote axis. Looking at the model it could be seen that when the gastrocnemius was shortened, there would be a flattening of the plantar arch, and that if these tissues were weak this arch would give way. The calcaneous variety of club-foot was exactly the reverse of flat-foot. In order that flat-foot should be produced, the motion should be blocked at or near a right angle.

Dr. S. L. McCurdy, of Dennison, Col., remarked that he had made some experiments, and had found that for graceful motion an ankle-joint was unnecessary.

Dr. Wirt said that the model was defective in that it represented one as walking with the foot perfectly flat.

Dr. Ketch said he did not agree with Dr. Wirt that

each time the body advanced, the heel was raised to the extent of causing contraction of the gastrocnemius.

DR. BARTOW said he had always thought that the flattening of the arch preceded the shortening of the muscles.

DR. HENRY LING TAYLOR said that flat-foot was a disease of relaxation, and the shortenings were consequent upon the position.

DR. S. L. MCCURDY then described a new method of excising the knee-joint, the object of which was to avoid injury of the extensors and the muscular structures composing the hamstrings and flexors. This was accomplished by a peculiar method of sawing the bone, and by the use of a special retractor or guide.

DR. ANSEL G. COOK read a paper on "Fixation and Traction in the Treatment of Fractures into Joints." He expressed the opinion that early passive motion only disarranged the fragments of bone, increased the production of callus, irritated the injured ligaments, and by increasing the inflammation tended to produce ankylosis. Immobilization was useful only during the active stage of inflammation, or until the broken ligaments and bones had become united; hence immobilization in a case of fracture into a joint should be kept up from three to eight weeks, and then massage employed.

DR. RYAN said it was his practice in fractures of the elbow to begin daily passive motion about the sixteenth day.

DR. E. G. BRACKETT, of Boston, said he had often increased the amount of motion by resting the parts in splints after passive motion had been too early or too vigorously resorted to.

DR. W. R. TOWNSEND, of New York, read a paper on "Tuberculous Disease of the Shoulder-joint." He stated that at the Hospital for Ruptured and Crippled, among 3244 cases of tuberculosis of bones and joints, 21 were of the shoulder-joint, 11 being in males and 10 in females. The disease had appeared at an average age of ten years. In five of the cases there was tuberculous disease of other joints, but in every instance the shoulder had been the last to be affected. The primary lesion was more likely to be in the bronchial tubes or lungs than in the bones. The symptoms were pain, reflex spasm, atrophy, change of contour of the parts, loss of function, enlargement of axillary glands, shortening of the arm, and ankylosis. The reflex spasm was the most important, and was well marked in the deltoid on abduction of the arm. Ankylosis, partial or complete, was the common termination. The average duration was two or three years. The condition might be mistaken for rheumatic arthritis, dislocation of the humerus, or osteomyelitis of the upper portion of the humerus. The prognosis should be considered from the effect on the constitution, as well as locally. Most of the cases presented partial ankylosis when first seen. There were two methods of treatment—one, simple immobilization; and the other, traction, with portable apparatus. Excision had been held to be dangerous, but the statistics were gathered from operations in the pre-antiseptic period. The growth of the humerus was largely from the upper epiphysis, and hence, in early life the removal of the epiphysis would stop the growth of the arm. With partial excisions, the mortality should be very low. In adults the tendency to pulmonary complications was greater; hence the disease should be removed as early as possible in them, if possible by a partial operation. The best operation was the subperiosteal one of Ollier. In children partial operations were more likely to give good results than mechanical treatment. The paper included a detailed account of seven cases of ordinary shoulder-joint disease.

DR. KETCH said he saw no more reason for operating in tuberculous disease of the shoulder-joint in children than in tuberculous disease of the other joints.

DR. SHAFFER said that he had treated these cases with a simple extension-brace, and with very satisfactory results.

DR. RYAN saw no occasion for operating on these cases any more than other cases of tuberculous disease of joints. His experience with mechanical treatment had been favorable in this class of cases.

DR. JOHN RIDLON, of Chicago, said he had always found the mechanical treatment very satisfactory, although he had not obtained such good results with Dr. Shaffer's traction-brace. His treatment had consisted in fastening the arm to the body, supporting the hand with a halter, and applying adhesive straps so as to still further immobilize the shoulder.

DR. HENRY LING TAYLOR, of New York, read a paper on "Infantile Scorbutus." He said that at a recent discussion no less than seventy cases had been reported. The symptoms were a dusky pallor, emaciation, excessive peevishness, and general sensitiveness; exquisitely tender swellings without local heat near the joints of the lower extremities, due to sub-periosteal hemorrhage; inability to move the lower extremities and trunk; spongy or bleeding gums near the erupted teeth; and most significant of all, rapid improvement on a diet of fresh milk and orange-juice. The peri-articular swellings, he said, had been frequently mistaken for rheumatism. Last summer a baby of a year old that had been fed on condensed milk had been brought to him for a supposed spinal or hip affection. There was a spinal projection in the upper lumbar region, with rigidity, in addition to the usual symptoms of scurvy. The cachexia, the spongy and bleeding gums, the powerlessness of the legs, the exquisite sensitiveness and a swelling above the right ankle made the diagnosis clear. All the symptoms disappeared within three weeks after putting the child on pasteurized milk and orange-juice. Other cases have been mistaken for hip-disease, osteitis of the knee, and sarcoma of the knee, and infantile paralysis.

DR. JOHN RIDLON, of Chicago, was elected President for the ensuing year.

NEWS ITEMS.

The American Electro therapeutic Association will hold its fourth annual meeting at the New York Academy of Medicine, September 25, 26, and 27, 1894. The following program has been arranged:

President's Address: Dr. W. J. Herdman, of Ann Arbor, Mich.

The Report of the Committees.—On Standard Coils: Dr. W. J. Morton, of New York. On Standard Meters: Dr. Margaret A. Cleaves, of New York. On Standard Electro-static or Influence Machines: Dr. W. J. Mor-

ton, of New York. On Constant Current Generators and Controllers: Dr. W. J. Herdman, of Ann Arbor, Mich. On Standard Electrodes: Dr. A. Lapthorn Smith, of Montreal. Stand and Electrode for Static Electricity—Exhibit: Dr. Lucy Hall-Brown, of Brooklyn. On Electric Light as a Therapeutic and Diagnostic Agent: Dr. Margaret A. Cleaves, of New York.

The Constant Current.—Physics: "Current Distribution," Mr. W. J. Jenks, of New York. Physiological Effects: Prof. H. E. Dolbear, of Boston. Therapeutic Uses—General: Dr. A. D. Rockwell, of New York. Gynecologic: "The Galvanic Current in Catarrhal Affections of the Uterus," Dr. G. Betton Massey, of Philadelphia. Suites éloignées du Traitement électrique Conservateur Gynécologie. Grossesses consécutives: Dr. Georges Apostoli, of Paris. Metallic Electrolysis: M. le Docteur Georges Gautier, of Paris; Dr. W. J. Morton, of New York; Dr. Margaret A. Cleaves, of New York; Dr. A. H. Goelet, of New York. Treatment of Urethral Stricture: Dr. Robert Newman, of New York. Diseases of the Eye—Electro-Therapeutics: Dr. L. A. W. Alleman, of Brooklyn, N. Y. Notes on Goiter and Improvements in Apparatus for its Treatment: Dr. Charles H. Dickson, of Toronto. Diseases of the Throat: Dr. D. S. Campbell, of Detroit. The Action of Electricity on the Sympathetic: Dr. A. D. Rockwell, of New York. Diseases of the Nervous System: "The Treatment of Neuritis by the Galvanic and Faradic Currents," Dr. Landon Carter Gray, of New York. Electric Sanitation: Prof. John W. Langley, of Cleveland. Physics of the Electric Light in Relation to Organized Matter: Prof. John O. Reed, of Ann Arbor, Mich. Hydro-electric Methods: "Physics and Appliances," Mr. Newman Lawrence, of London. Special Hydro-electric Applications: Dr. Margaret A. Cleaves, of New York. The Hydro-electric Therapeutics of the Constant Current: Dr. W. S. Hedley, of Brighton, England.

Induction Currents.—Physiologic Effects: Dr. W. J. Engelmann, of St. Louis, Mo. Therapeutic Uses—General: "General Faradization," Dr. A. D. Rockwell, of New York; Dr. A. H. Goelet, of New York. Gynecologic: Dr. H. E. Hayd, of New York; Dr. A. Lapthorn Smith, of Montreal.

Sinusoidal Currents.—Physics: Mr. A. E. Kennelly, of Philadelphia. Physiologic Effects: Dr. W. J. Herdman, of Ann Arbor, Mich.; Dr. J. H. Kellogg, of Battle Creek, Mich. Therapeutic Uses: Dr. Margaret A. Cleaves, of New York; Dr. William James Morton, of New York; Dr. J. H. Kellogg, of Battle Creek, Mich.; Dr. Holford Walker, of Toronto; Dr. A. H. Goelet, of New York. Le Courants Alternatifs; leur Transformation; leur mesure et leurs Application thérapeutiques: M. le Docteurs Gautier et Larat, of Paris. On the Sinusoidal-Current Methods of Regulation, the E. M. F. and Resultant Current: Dr. Lucy Hall-Brown, of Brooklyn, N. Y.

Static and Static Induced.—Physics: Prof. Edwin J. Houston, of Philadelphia. Therapeutic Uses: "General Therapeutic Uses," Dr. William James Morton, of New York. The Treatment of Chorea: Dr. D. R. Brower, of Chicago. Static Induced: Dr. Margaret A. Cleaves, of New York. High Frequency Currents derived from Static Machines as per Method d'Arsonval: Dr. J. H. Kellogg, of Battle Creek, Mich.

In Memoriam.—Dr. Wm. F. Hutchinson, Providence, R. I., and Dr. John Chambers, Indianapolis, Ind. (Dr. Robert Newman, of New York); Dr. Plymon S. Hayes, Chicago (Dr. W. J. Herdman, of Ann Arbor, Mich.).

The American Association of Obstetricians and Gynecologists will hold its seventh annual meeting at Toronto, Ont., September 19, 20, and 21, 1894. The following preliminary program has been arranged: (1) President's Address, George H. Rohé, Catonsville, Md.; (2) Personal Experience with Pus Tubes: When to Operate, How to Operate, and the Results of Operation, Jas. F. W. Ross, Toronto, Ont.; (3) Relation of Hysteria to Structural Changes in the Uterus and Adnexa, A. P. Clarke, Cambridge, Mass.; (4) Demonstration of a Mechanism of Intussusception (Rabbits), Robert T. Morris, New York; (5) Nephrectomy, L. H. Dunning, Indianapolis; (6) Treatment of Distention of the Fallopian Tubes without Laparotomy and Removal, Frank A. Glasgow, St. Louis; (7) Hysteria in Pregnancy, W. P. Manton, Detroit, Mich.; (8) Relations of Renal Insufficiency to Operations, Carlton C. Frederick, Buffalo, N. Y.; (9) *a*, Importance of Recognizing Septic Puerperal Endometritis Early, and Its Treatment; *b*, Demonstration of a Portable Operating Table for Gynecological and Abdominal (Trendelenburg) Work, Edward J. Ill, Newark, N. J.; (10) Suspension of Retroflexed Uterus by the Utero ovarian Ligaments, with Report of Cases, Reuben Peterson, Grand Rapids, Mich.; (11) The Element of Habit in Gynecic Disease, Geo. F. Hulbert, St. Louis; (12) Some Results of Ether-Anesthesia in Abdominal Operations, I. S. Stone, Washington, D. C.; (13) Report in Abdominal Surgery, Presenting Cases, A. Vander Veer, Albany; (14) Supplementary Paper on Abdominal Section in Intrapelvic Hemorrhage, M. Rosenwasser, Cleveland; (15) Conservative Midwifery, J. M. Duff, Pittsburg; (16) The Cause of the Thirst Following Abdominal Section, Eugene Boise, Grand Rapids, Mich.; (17) The Care of Pregnant Women, W. B. Dewees, Salina, Kan.; (18) Subject to be announced, L. S. McMurtry, Louisville, Ky.; (19) *Discussion*—Inflammatory Diseases of the Uterus and Appendages and of the Pelvic Peritoneum. (*a*) Introductory Remarks, William Warren Potter, Buffalo; (*b*) Historical Sketch, Edward J. Ill, Newark, N. J.; (*c*) Clinical History, Charles A. L. Reed, Cincinnati, O.; (*d*) Causation and Pathology, Lewis S. McMurtry, Louisville, Ky.; (*e*) Diagnosis and Prognosis, James F. W. Ross, Toronto, Can.; (*f*) Treatment, M. Rosenwasser, Cleveland, O.; A. Vander Veer, Albany, N. Y.; J. H. Carstens, Detroit, Mich.; A. H. Cordier, Kansas City, Mo.; (*g*) Results (a) When Treated; (b) Under Various Methods of Treatment, Joseph Price, Philadelphia, Pa.; (20) Intercurrent Typhoid Fever in Pregnancy, Thomas E. McArdle, Washington, D. C.; (21) Notes on a Case of Cholelithiasis, Frederick Blume, Allegheny, Pa.; (22) Perineal Operations, Joseph Price, Philadelphia.

The Cholera and the Plague.—It is reported that cases of cholera have appeared at Berlin and at Nantes. Four cases of cholera and three deaths have been reported at Adrianople. It is announced on competent authority that the epidemic prevailing in China is the bubonic plague, and of most malignant type.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXV. SATURDAY, AUGUST 4, 1894. No. 5.

ORIGINAL ARTICLE.

THE COMPARATIVE RARITY OF PULMONARY TUBERCULOSIS IN THE HIGHLANDS OF PENNSYLVANIA AND THE ADJACENT COUNTIES OF NEW YORK.[1]

BY GUY HINSDALE, A.M., M.D.,
LECTURER ON CLIMATOLOGY IN THE UNIVERSITY OF PENNSYLVANIA; FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

IF the profession were asked what district in the New England or Middle States showed the greatest immunity from pulmonary tuberculosis, the answer would probably be "The Adirondack Mountains." Without, however, disparaging that great health-resort, where such remarkable opportunities for pleasure and recuperation are afforded to the tens of thousands that flock there—a resort to which I am personally deeply attached—I would, nevertheless, call attention to a region much nearer the homes of many of us; in most respects more suitable for continuous residence, and apparently even more healthful than the Adirondack region itself.

The district referred to falls partly within the State of New York and partly within Pennsylvania. The seven counties along the southern border of New York are Chautauqua, Cattaraugus, Allegany, Steuben, Chemung, Tioga, and Broome. The neighboring region in northern Pennsylvania includes the counties of McKean, Potter, Forest, Clarion, Elk, Cameron, Union, and Sullivan, and at some distance to the eastward, Pike County. In all of this region, comprising over 12,000 square miles, nearly equally divided between New York and Pennsylvania (6545 miles in New York, 5557 in Pennsylvania), there is, according to the best available information, a population of over 1000 persons to each annual death from pulmonary tuberculosis. I confess I was somewhat surprised to discover that in New York State the southern tier of counties from Broome westward make the best returns.

Taking the reports of the State Board of Health for 1893, I find that in the maritime district, including New York, Westchester County, and Long Island, there are 400 persons living for every annual death from pulmonary tuberculosis; in the Hudson River district, 550. Next in order comes the Mohawk Valley; then the Lake Ontario and western region; next the central counties; then the Adirondack and northern district, in which there are from 854 to 985 persons living to one death from pulmonary tuberculosis; and finally and best of all, in New York the seven counties of the southern tier, with 1091 persons living to each death from pulmonary tuberculosis. The accompanying map shows this relative prevalence of pulmonary tuberculosis in the State of New York.

During each of the last four years the mortality from pulmonary tuberculosis in the southern tier of counties in New York, in comparison with the total deaths, is far below what obtains in other portions of the State. This is clearly illustrated by the annexed chart. It is evident that from whatever standpoint we look at the subject, the southern tier of counties are the freest from pulmonary tuberculosis.

Among the characteristics of this region are the following:

Population. Sixty-two persons per square mile; engaged chiefly in agriculture.

Soil. Highly productive. Geologic formation, limestone and sandstone.

Products. Hay, oats, potatoes, grapes, standing timber.

Temperature. The mean annual temperature in 1892 was 44.5°, or six and one-half degrees less than in New York City, and three and one-half degrees more than in the Adirondack region. The latest killing frost occurred on April 26th at Jamestown, and the first frost November 5th; this was about the same as in New York, and gave an agricultural season twenty-four days longer than in the Adirondack region.[1]

Rainfall. This varies from 37 to 47 inches annually in the southern tier. The amount is usually less than in other portions of the State.

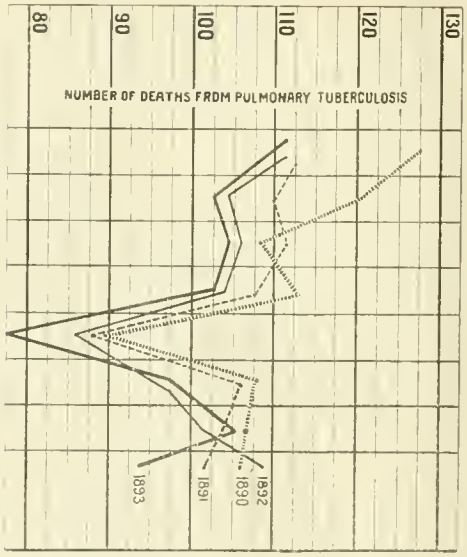
Elevation. In the southern tier of counties the following elevations are noted:

Alfred Center, 1820 feet; Angelica, 1340 feet; Friendship, 1550 feet; Binghamton, 860 feet; Nineveh, 1032 feet; Humphrey, 1500 feet; Sher-

[1] Read at the annual meeting of the American Climatological Association at Washington, D. C., June 1, 1894.

[1] The stations in the southern tier district reckoned were Jamestown, 47°; Alfred Centre, 43°; Angelica, 43°; South Canisteo, 43°; Addison, 45°; Hammondsport, 43°; Binghamton, 54°; Humphrey, 50°.

In the Adirondack district the stations are Lyon Mountain, 39.2°; Malone, 41°; "Number Four," 40°; and stations in Essex and St. Lawrence counties, 42°.



MARITIME DISTRICT.
Population, 3,200,950—per cent. city population, 87.17.

HUDSON VALLEY DISTRICT.
Population, 684,263—per cent. city population, 40.31.

ADIRONDACK AND NORTHERN DISTRICT.
Population, 386,680—per cent. city population, 7.50.

MOHAWK VALLEY DISTRICT.
Population, 376,116—per cent. city population, 30 93.

SOUTHERN TIER DISTRICT.
Population, 405,967—per cent. city population, 26.85.

EAST CENTRAL DISTRICT.
Population, 386,600—per cent. city population, 23.75.

WEST CENTRAL DISTRICT.
Population, 311,000—per cent. city population, 12.28.

LAKE ONTARIO AND WESTERN DISTRICT.
Population, 761,756—per cent. city population, 60.60.

man, 1568 feet; Elmira, 863 feet; Savona, 1053 feet.

It will be noted that these elevations are somewhat below those of the stations in the adjacent district in Pennsylvania, to be considered later.

Position with reference to storm-tracks. The region considered is the farthest removed in New York State from the path of greatest frequency of storms. These are prone to pass down the valley of the St. Lawrence. This southern region is thus spared some of the cloud and rain accompanying the moving areas of lowest barometric pressure.

Accessibility and accommodations. All points in this region are reached by the New York, Lake Erie and Western Railroad, and desirable accommodations may be found about Chautauqua Lake and Jamestown.

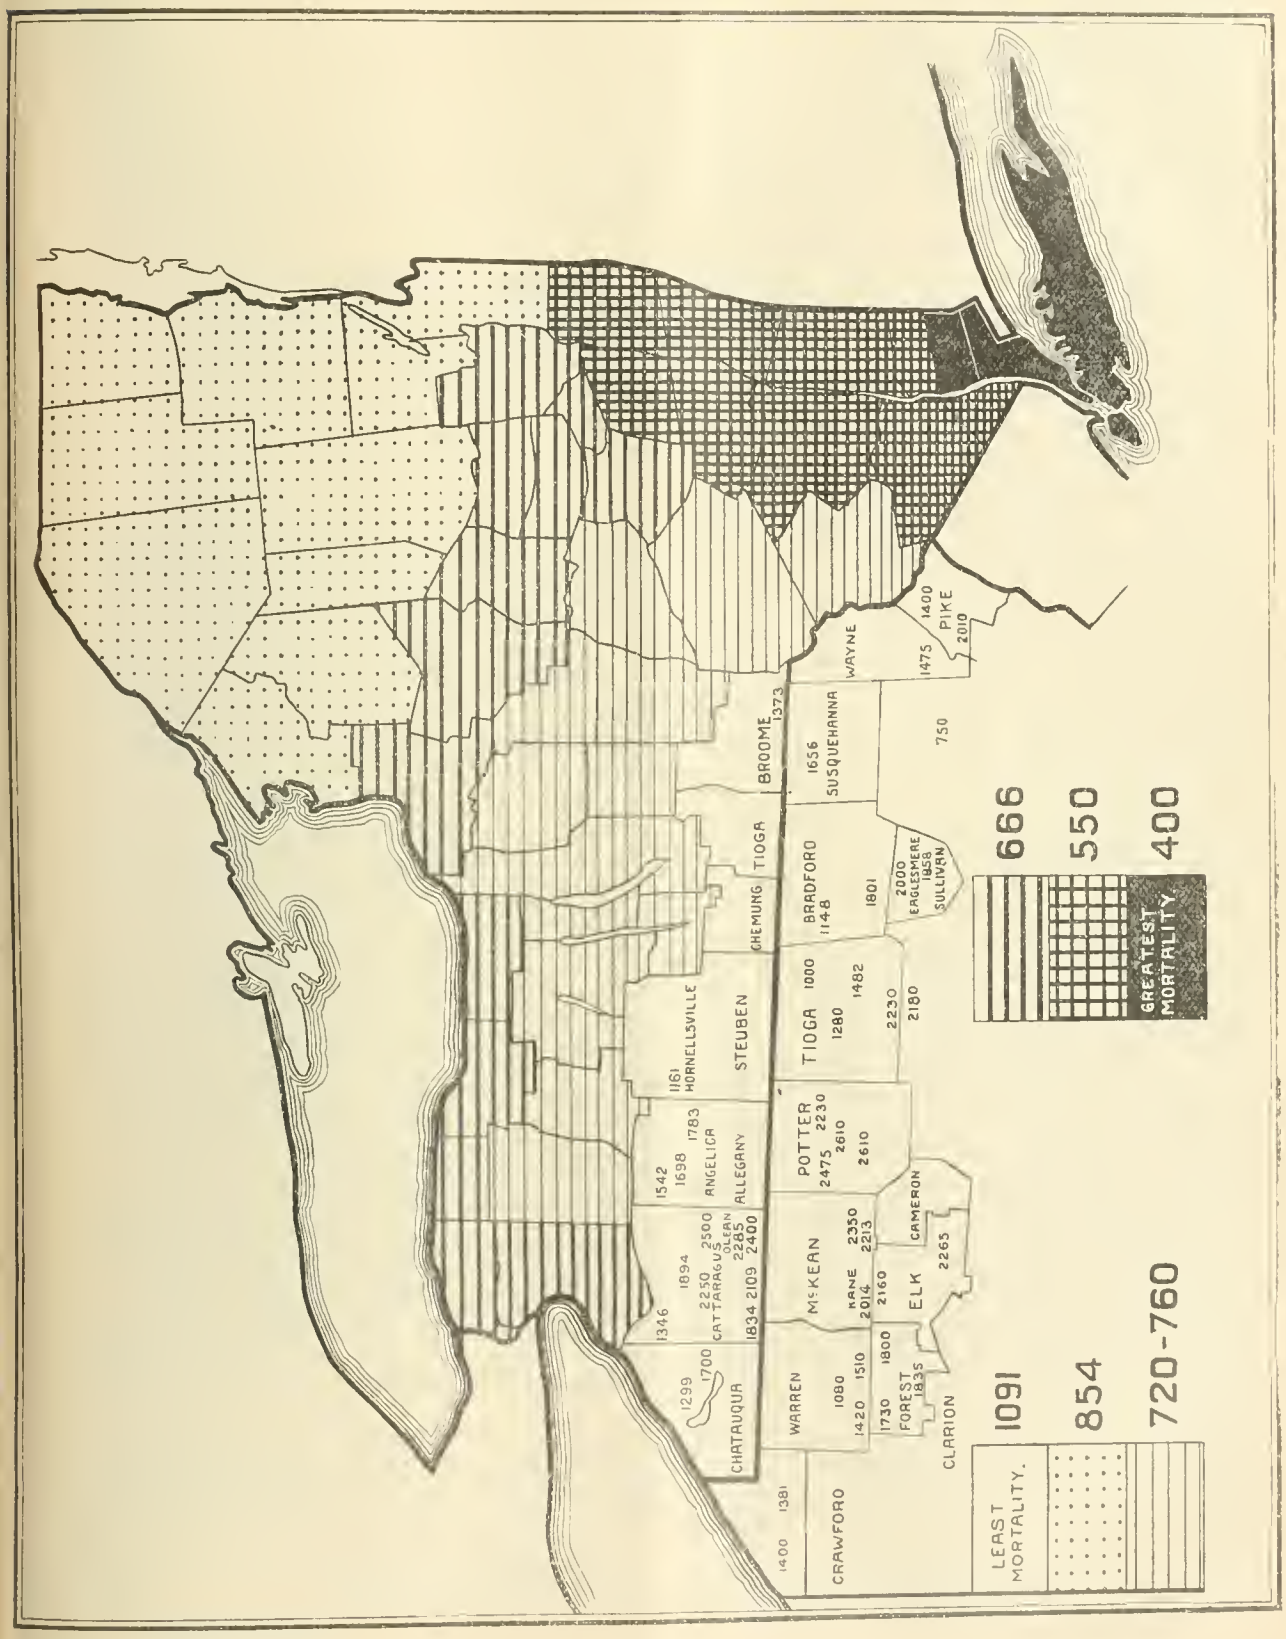
No special claim has been made for this region with reference to the climatic treatment of pulmonary tuberculosis; but in Chautauqua, Cattaraugus, Allegany, and Steuben counties a new and uncontaminated field is opened for the treatment of tuberculous patients, with many opportunities for self-support not found elsewhere.

The Highlands of Pennsylvania adjacent to the New York border are of a somewhat different physical character. The country is wilder, the forests more extensive, the general elevation greater; it is a little cooler, a little drier, a little more primitive. Agriculture is not nearly so remunerative; the industries are more prominently lumbering and mining for coal, iron, and oil. Vast areas of hemlock, and here and there growths of pine cover the mountain-tops, while there are many ridges timbered with beech, birch, and maple. The climate is superb during the months of May, June, July, August, and September; it is distinctly bracing, with the sunshine of more southern latitudes. Cold weather usually sets in about November 1st, and continues in what is called a "solid winter" until the following April. For nearly four months there is usually good sleighing. A temperature of zero is not felt to the same degree as the freezing-point in most places where there is fog, where the air is less dry and bracing, and where the rainfall is greater and the soil more retentive of moisture. Pleurisy and pneumonia are uncommon, and epidemics of diphtheria and scarlet fever are said never to occur. A physician in McKean county writes me: "I have seen but three cases of true diphtheria during my fifteen years' residence here. I have never known a case of pulmonary tuberculosis to originate here, and the cases that come here are greatly benefited or entirely cured."

The broad and high table-land in northwestern Pennsylvania has great topographic advantages over the surrounding region, in that its surface is not so deeply cut by water-courses. The counties of McKean, Forest, Elk, and Clarion comprise the highest ground; the streams take their rise from this "Big Level," as it is called; they are still small and have not produced the deep gullies and narrow valleys which are a common feature throughout northern Pennsylvania.

In the outlying region the chief settlements are necessarily found along these water-courses, while the uninhabited mountain-tops, far above the foggy and fertile valleys, are rarely visited except by lumbermen.

In Sullivan County deep indentations penetrate its entire area; nevertheless, we find on one of the mountain-tops two beautiful lakes, about which are clustered the summer homes of many who have discovered the great benefit to be derived from a



Map Showing the Distribution of Pulmonary Tuberculosis in the State of New York and Adjacent Counties of Pennsylvania.

The small numerals in the map indicate the altitude; the large figures below, the average number of persons living to each annual death from pulmonary tubercu-

residence in this attractive region.[1] The table-land of McKean, Forest, Elk, and Carbon counties is not so diversified, therefore the scenery is not so striking. On the other hand, the county has certain advantages. The timber is of more primitive growth and covers a greater extent; the air is drier and pulmonary tuberculosis is found to be less prevalent. McKean County carries off the palm in this respect. The last and only trustworthy data on this point were afforded in 1880, when it was found that 1330 persons were living to each death from pulmonary tuberculosis during the year. This was a much smaller mortality than obtains in the southern counties of New York (1091 living to each death from pulmonary tuberculosis), and less than one-fourth of that which is annually recorded in New York City and Philadelphia.

The great desideratum in the climatic treatment of pulmonary tuberculosis is a region unfrequented by tuberculous subjects; a country that affords, at moderate elevation, a stimulating climate; a dry and therefore a permeable soil; an evergreen forest; a clear sky, and ample opportunities for out-of-door life. The Highlands of Pennsylvania, and especially McKean County, provide all of these features. Kane, in the southwestern corner of McKean County, has already acquired some reputation as a desirable summer-resort. Personal testimony from patients who have gone there has been exceedingly gratifying, and I have no hesitation in recommending a residence in this locality for all cases of pulmonary tuberculosis in at least the first and second stages.

In order to be utilized to the greatest advantage the patient should reach his destination in the late spring or early summer. He should become acclimated during the milder portion of the year, when the new surroundings make the most favorable impression upon his mind; when in his walks and drives, and in his intercourse with the resident population he is able to form those attachments to persons and things that go so far to incline him to stay beyond the period when most summer visitors are compelled to leave. The fine autumn days in northern Pennsylvania may be to him the most enjoyable and profitable season; the winter, with its abundant snow, unbroken by changes of temperature so common at the seaboard, will be well adapted, under intelligent supervision, for his open-air treatment.

There is no question in my mind that all the good that has been accomplished at the Adirondack Cottage Sanitarium might be repeated in Pennsylvania, and many lives be saved to the Commonwealth. A good hotel, easy walks and pleasant drives, and a convenient railroad constitute the present accommodations; but I hope that the time will come when either the State, in its generous provision for charitable institutions, or else private philanthropy, which seems never to tire of establishing new hospitals in cities, will turn a pitying eye on the tuberculous patient so that he may have the purest air under heaven, and the same skilful and sympathetic treatment that are so generously given to others.

ORIGINAL ADDRESS.

THE PATHOLOGIC CHANGES CAUSED BY CERTAIN SO-CALLED TOXALBUMINS.[1]

An Experimental Study.

By SIMON FLEXNER, M.D.,
OF BALTIMORE, MD.;
ASSOCIATE IN PATHOLOGY, JOHNS HOPKINS UNIVERSITY.

The crystalline principles called ptomaïns which have been isolated by Selmi, Nencki, Brieger,[2] and others from cultures of bacteria do not, as was once supposed, represent the essentially active agents produced by pathogenic bacteria. Since the isolation by Roux and Yersin[3] in 1888, from cultures of the bacillus diphtheriæ, of an amorphous toxic albuminous substance which, as they showed, was capable of causing all of the symptoms of diphtheria, excepting the pseudo-membrane, other albuminous substances have been obtained from a number of pathogenic bacteria.

The researches of Kobert and Stillmark,[4] Martin,[5] and Hellin[6] have led to the isolation from the castor-bean and the jequirity-bean of two amorphous substances—ricin and abrin respectively—which in many respects resemble the toxic albuminous principles obtained from bacteria.

We owe to the investigations of Weir Mitchell and Reichert[7] the knowledge that the toxicity of snake-venom depends upon certain albuminous constituents, and later Mosso and Springfeld[8] separated from the blood of eels an exquisitely poisonous albuminous substance. Moreover, the well-known effects which the blood-serum of one species of animal exerts upon another species has led to the conclusion[9] that the blood of different animals contains distinctly toxic substances.

As to the precise nature of many of these substances, to which the name of toxalbumins has been provisionally given, there is little agreement. They are regarded by some investigators as being enzymes, while a few deny altogether their albuminous nature.

It has been suggested by Roux and Yersin that the

diphtheria-toxalbumin is an enzyme, and Stillmark holds the same view concerning ricin, while Nencki[1] considers that the proteids of the blood-serum, to which it is believed by many that animals owe their immunity from disease, belong to the same category.

The recent statement of Brieger and Cohn,[2] based upon the study of the properties of a highly refined tetanus-toxin, that this body, which fails to react with Millon's reagent, and responds to the xantho-proteic test, is not an albumin, is not regarded as sufficient to disprove its proteid nature.[3]

Brieger and Fränkel[4] oppose the view of the enzyme-nature of these bodies; and Fermi,[5] who also objects to this view, considers as militating against it the fact that of 114 described pathogenic microörganisms which produce toxins, only 26 produce proteolytic ferments, and that, on the other hand, of 134 known enzyme-producing bacteria only 25 are pathogenic—that is to say, toxalbumin-producing.[6]

The blood-serum of the dog acts with great energy upon the red blood-corpuscles of the rabbit, and Buchner[7] observed that while the blood-serum of these animals is separately capable of destroying a considerable number of typhoid-bacilli, yet when the serum of the dog and rabbit are mixed, the destructive influence of the mixture upon typhoid-bacilli is less than that possessed by either serum alone. As bearing on this question, the experiments of Robert Hartig[8] on the fungus-parasites of plants are interesting. Thus, while certain of the ferments of this origin dissolve the cellulose of plants and not the intercalated wood-gum, there are others that dissolve the gum and have no effect upon the cellulose. According to Hartig the oak is attacked by ten distinct parasites, each of which produces a different ferment. Two of these dissolve starch—are amylolytic—when acting separately, but when combined they are entirely without action on this substance. Does this not suggest an analogy with the mutual destruction or neutralization of the bactericidal principles of the blood of the rabbit and the dog?

Further, we have grounds for believing that the blood possesses the power of destroying the true ferments, as it does certain of the bacterial products, and, moreover, that the true ferments may act in a manner similar to the vegetable toxalbumins in conferring immunity. Hammersten[9] has shown that if rennet and milk are injected separately into the circulation of rabbits the coagulating influence of the ferment upon the milk is much diminished; and Hildebrand[1] has demonstrated an antiferment in the blood of animals rendered immune to certain of the enzymes, especially to emulsin. He[2] has succeeded, moreover, in rendering rabbits more resistant to the bacillus cuniculicida, and even of protecting them against the organism by previously inoculating them with and making them immune to emulsin.

Heating solutions of many of the toxalbumins or blood-serum to 60° C. destroys their activity. Blood-serum kept for thirty minutes at a temperature of 55° C. loses, according to Buchner, its power to destroy bacteria and likewise its globulicidal action. Exposed to a temperature of 54° C. for the same time I have found that dog's serum is still globulicidal for rabbits, although its activity is diminished.

Blood-serum that has lost its bactericidal and globulicidal properties by being kept at a temperature of 60° C. for thirty minutes has not suffered coagulation, nor have demonstrable optic or chemic changes occurred in it. The lost bactericidal property, it is believed by Emmerich and Tsuboi,[3] can be restored by alkalinization and dialysis, a circumstance that they bring forward as bearing upon the question of the chemic *versus* the vital action of the serum. Buchner,[4] it must be mentioned, disputes the results of Emmerich and Tsuboi and claims that the difference that they observed in the effects of the heated serum before and after alkalinization is explicable on other grounds, as, for example, the alteration in the heated serum as a culture-medium. None of these authors, however, mentions the effect of this treatment upon the globulicidal property of the serum, and to determine this I have made the following experiments:

The blood-serum[5] of a dog, collected after twenty-four hours, was tested as to its toxicity, by injecting 1.5 per cent. of the body-weight into the ear-veins of a rabbit. The animal was profoundly affected, soon manifested hemoglobinuria, and died in ten hours.

A second half-grown rabbit, whose blood-count at 11.15 A.M. was 6,080,000 red corpuscles to the c.mm., received 1 per cent. of its weight of unheated serum. It was dead in five minutes, from thrombosis of the right side of the heart. A second-blood-count, made from the lake-colored blood of the left ventricle taken during the death-struggle, showed 3,872,000 red corpuscles per c.mm.

A third control-rabbit received 1 per cent. of its weight of the same serum heated to 55° C. for one hour, without any effect whatever.

Seventy-five c.cm. of the heated serum were now made alkaline with 7.5 c.cm. of a 3 per cent. solution of pure caustic soda and dialyzed through gut for forty-three hours against seventy-six liters of normal salt-solution. The whole volume of serum now equalled 90 c.cm.

A white-mixed rabbit weighing 1600 grams, whose blood-count on March 21st was 5,664,000, and on March 22d 6,368,000 per c.mm., received at 10.20 A.M. an amount of dialyzed serum which corresponded to 1 per cent. of the body-weight of the original serum (16 c.cm. of the original = 19.5 c.c. of dialyzed serum). No immediate effect was produced. At 11.10 A.M. the blood-count was 4,938,000 per c.mm. No hemoglobinuria or other unfavorable symptom had appeared. On April

[5] In all cases in which blood-serum was used the drawn blood was placed upon ice immediately after having been obtained.

11th the rabbit was still alive and apparently well, the blood-count on this day showing 5,856,000 per c.mm.

Another rabbit, weighing 1800 grams, whose blood-count on March 21st was 6,112,000 per c.mm., and on March 22d 6,208,000, received at 10.30 A.M., March 22d, 1.5 per cent of its body-weight (27 c.c. of the original = 32.5 c.c. of dialyzed serum) of the dialyzed serum. At 11.25 the blood-count was 5,180,000 per c.mm. At 2 P.M. this rabbit, which appeared perfectly well, received a second quantity of 1.5 per cent. of its body-weight. The blood-count at 3 P.M. showed 4,980,000, and on April 11th, at which time the animal appeared normal, it was 5,952,000.

The second animal, it will be noted, received double the certainly lethal dose of the normal, unheated serum, with relatively slight effect. From these experiments it must be concluded that the globulicidal action of the serum is certainly not entirely restored, and if at all, to a minor degree only, by alkalinization. The animals are still living and so far show no evidence of the toxic effects of the serum. Hence, it would appear that the toxic properties are also lost at this temperature.

In considering the pathologic action of the toxic proteids derived from the several sources mentioned upon susceptible animals we shall find reason to treat of them together. Let us consider for a moment the production of immunity, which, for many bacteria and their products, is such a well-known fact that it need not detain us; and evidence is not wanting for the albumins derived from the higher plants, the phytalbumoses.

Up to the present time no one has succeeded in rendering animals permanently immune to the animal toxic proteids, although Sewell[1] claims to have secured in pigeons an immunity to snake-poison which, however, disappeared after a time.

Ehrlich[2] has shown that mice, which are relatively quite susceptible to ricin and abrin, can be rendered in a high degree immune to the action of these bodies. As concerns ricin, he found that a solution having a concentration of 1 to 750,000, in the quantity of 1 c.c. per 20 grams of weight will often kill mice in from two to four days; and in the same dose a solution of 1 to 200,000 will kill these animals without exception. The local effect of the drug is so intense that it is necessary to resort first to feeding, by which means a low grade of immunity is established, which can then be increased by subcutaneous inoculations. The immunity appears quickly. I have repeated Ehrlich's experiments and have confirmed his results.

For example, two mice were fed with gradually increasing doses for ten days, and at the end of this time an immunity equal to the natural resistance of five, as determined by subcutaneous inoculations with control-animals, was already present. From now on the doses were rapidly increased, so that on the twelfth day the resistance was equal to ten; on the sixteenth, to eighty; on the eighteenth, to one hundred and forty, and on the twentieth day, to two hundred and fifty.

These figures are all low, as the calculation is based on the surely lethal dose of 1 to 250,000, and the highest grade of immunity was not determined. Even at this time the immune animals were found not to be indifferent to the mode of introduction; for of two mice, which up to this point had acted in all respects alike, one was inoculated into the peritoneal cavity, and died in one and a half hours, while the other, after subcutaneous inoculation with the same amount (1 c.c. of a 1 to 1000 solution), became slightly sick, but was perfectly well the next day. The blood of the mouse that succumbed was laky. The blood of immune animals, *i. e.*, in a condition that Ehrlich denominates ricin-proof, contains an antitoxic body, which by simple admixture outside the body with a solution of ricin is capable of rendering the latter innocuous.

Having in mind the production of immunity to this substance, I have experimented on rabbits with dog-serum, but so far without success. On the contrary, I found that animals that had withstood one dose of dog's serum would succumb to a second dose, given after the lapse of some days, or weeks, even when this dose was sub-lethal for a control-animal.

Two rabbits received ½ of 1 per cent. and 1 per cent. of their body-weight respectively of dog's serum, twenty-four hours old, on January 19, 1894. With the exception of hemoglobinuria, indisposition to move, and increased respiration, no ill-effects were noted. The animals still showed hemoglobinuria on the following day. These symptoms disappeared, and apparently the rabbits entirely recovered. On February 12, 1894, each received 1 per cent. of their body-weight of dog's serum intravenously. A control-animal also received 1 per cent. of its body-weight of the same serum. The two animals that had been previously inoculated died in two and twelve hours respectively; the control-animal showed only hemoglobinuria, which disappeared after a day or two.

The pathologic lesions produced in animals by these various poisonous substances have been very imperfectly studied up to the present time. The contributions that have been made to this subject refer almost exclusively to the gross changes in organs and tissues, or consider simply the effect that is produced upon the blood, especially the alterations in coagulability. Hellin, who studied, he says, one hundred organs or parts of organs obtained from animals dead of abrin-poisoning, could discover nothing abnormal, except thrombi composed of red blood-corpuscles. The whole pathologic process in these cases has been considered to depend upon an active gastro-enteritis, thrombosis of the vessels of the stomach and intestine, necrosis and ulceration from digestion. To this is to be added, for those cases in which death occurs rapidly with symptoms of convulsions, thrombosis of the cerebral vessels. Just as little attention has been given to the tissue-changes caused by the inoculation of animals with foreign serum. Heretofore it has sufficed to consider as the cause of death in the immediately fatal cases the coagulation of the blood, especially in the right heart and main pulmonary vessels, or the production of widespread capillary thrombosis. All experimenters have, however, encountered cases in which, as death has been delayed for several days, this explanation was insufficient, as thrombi were not demonstrable. Ponfick has shown that the kidneys suffer injury in secreting the hemoglobin liberated by the breaking up of the red blood-corpuscles, and he attributes many cases of death to the resulting nephritis and blocking of the kidney-tubules with methemoglobin casts.

It will be my especial purpose to point out the insuf-

[1] Journal of Physiology, 1887.

[2] Deutsche med. Wochenschrift, 1891.

ficiency of these views. A study of the pathologic changes in the organs has convinced me that the extent, and not the absence of tissue-alterations, is most remarkable.

At this time there are comparatively few that accept the bacterial origin of disease who will question the mode in which the organisms act, *i.e.*, whether it is the presence of the bacteria as such in the tissues, or the products of their vital activities, that is responsible for the harm that is done. Neither the mechanical influence, nor the effects of depriving the body of a certain quantity of oxygen and albumin, will longer suffice to explain their action. It is true that as living beings the bacteria require certain materials in order to build up their bodies and maintain their functions, and these they secure from the available stores of their surroundings, but it is just as certain that in the performance of their activities they produce excrementitious substances, which are in turn discharged into the host. It is to these substances, of which we have already spoken, that the attention of chemists and pathologists has of late been directed. And the study of their composition and properties has not only brought much light into this field of work, but has opened up new avenues of investigation, at the same time awakening new and unexpected hopes for the future of therapeutics.

It is now some three years since Professor Welch and myself[1] published a short communication on the lesions produced in the tissues by the soluble products of diphtheria-bacilli. This paper, following one describing the histologic lesions in kittens, guinea-pigs, and rabbits caused by the inoculation of the bacilli themselves, confirmed in all essential respects the first paper.

The study of the relation of the bacillus diphtheriæ to the disease diphtheria indicated that the constitutional symptoms of the disease, which, in human beings, are often of the gravest nature, were due to an absorbed poison, and not to the organisms themselves. The separation of the poison from cultures in a dry, but impure state, by Roux and Yersin, and the reproduction through its agency of the constitutional symptoms, including the paralysis, of the disease may be said to have been conclusive. Yet it remained to find in the animals experimented upon lesions similar to or identical with those described by Oertel in human beings.

I shall not here undertake to give an account in detail of these changes. They have since been seen and studied by a number of investigators, and constitute an additional link in the chain of evidence of the causal relation of the bacillus diphtheriæ to diphtheria in human beings. But I wish to state that these lesions are found extensively in the tissues. They are present in the lymphatic glands generally, in the spleen, liver, intestinal canal, kidney, and heart-muscle, and are characterized by a death of cells in the affected parts. Strangely enough, the peculiar changes are not equally distributed throughout the affected organs, as one would naturally infer when it is considered that we have to deal with a soluble substance circulating in the blood; but in the lymph-glands and viscera these lesions tend to occur in well-marked areas or foci.

This, then, has brought us face to face with a new problem in pathologic histology. Heretofore we were wont to separate the focal from the diffuse lesions. The latter class, such as commonly attend infections and intoxications, we have long since learned to know under the term given it by Virchow, of "parenchymatous degeneration," the "cloudy swelling" of the older writers. This is the type of lesion that was believed to result from the action of a soluble poisonous substance, in a certain concentration when the influence is continued for some time. The focal lesions, such as tubercle, a focal abscess, were regarded as the result of the lodgment and increase of the particular injurious agent in the areas affected.

Nor are we required to alter our views of the relation of the focal lesions in diphtheria to the soluble poison by the observation of Frosch,[1] since confirmed by several others, that in human beings a few diphtheria-bacilli are often found in the liver, the spleen, and other organs. The number of organisms is, in the first place, altogether insufficient to explain the lesions; there is, moreover, an entire absence of evidence of relation between the organisms and the tissue-changes, and, finally, there are cases in which no organism can be demonstrated, and, in animals, we now know that they are not necessary to the production of the focal lesions.

But I wish to present still more conclusive evidence of the relation between soluble poisons and focal lesions. For example, certain lesions ought long ago to have led to the suspicion that even soluble substances may act upon one part of the body and not upon another.

Consider, for instance, the action of snake-poison. What could be more impressive than the production of capillary focal extravasations of blood in the serous membranes in consequence of a subcutaneous inoculation of the poison? In this case the action of bacteria or other essentially "living agent" can, by the experiments of Mitchell, Reichert, Formad, and others, be entirely excluded.

I have made a series of experiments with poisons of another kind. From the published accounts of the action of ricin and abrin upon animals, little can be learned concerning the minute pathologic changes induced by these bodies. Manifestly these substances offer an opportunity to study the question of the relation of soluble poisons to focal lesions. In them we have, as I have already shown, substances that in many respects resemble the bacterial poisons; and according to Martin, the action of abrin is suggestive of snake-poison. They thus seemed to constitute ideal substances for study.

The first experiments which I made showed me that the picture of the pathologic changes given by Kobert, Hellin, Stillmark, and Ehrlich was very incomplete. In the main, subsequent work enabled me to confirm their results; but they have overlooked, it seems to me, the most striking and significant changes.

The samples of ricin and abrin which I employed in my experiments were made by Merck. The substances, which are supplied in the form of grayish-white amorphous powders, are insoluble in water, but dissolve readily and completely in a 10 per cent. salt-solution. After solution they can be diluted without change by addition of physiologic salt-solution or distilled water.

One of the impressive results in the use of these bodies

[1] Johns Hopkins Bulletin, 1891.

[1] Zeitschrift f. Hygiene u. Infektionskrankheiten, Band xiii, Heft 1, p. 49.

was the certainty of their action. After one has experimented with bacteria, the virulence of which is open to fluctuation, this constancy of action is a very striking characteristic. In this respect, again, we can see an analogy with snake-poison. Kobert has pointed out that 0.03 mg. per kilogram of ricin is fatal to rabbits and cats, and probably dogs, if injected into the veins, and Ehrlich has shown that guinea-pigs are so susceptible that one gram of the substance would suffice to kill not less than 1,500,000 of these animals.

My experiments have been completed only so far as to enable me to report upon the effects produced upon mice, guinea-pigs, and rabbits. I have had among these animals very acute and chronic cases. The acute cases present such a characteristic clinical and pathologic picture as to be unmistakable.

The lesions about to be described could be produced almost with the certainty of a chemic reaction.

I shall not give the detailed protocols of the cases, but will content myself with a description of the pathologic changes in general, and shall, in the first place, summarize a few typical cases.

The intra-venous inoculation of ricin dissolved in 10 per cent. salt-solution in the proportion of 0.3 mg. to 3 mg. per kilogram of weight kills rabbits in from eighteen to twenty-six hours. In the cases of most rapid death, the axillary, inguinal, bronchial, and cervical lymphatic glands are found slightly swollen and softened. The peritoneal cavity may or may not contain an excess of clear fluid; the mesenteric glands at the attachment of the mesentery are also swollen and edematous. The intestines, especially the small intestine, are distended and pale, their contents being soft, glutinous, and grayish-white in color, and resembling in appearance cholera-stools. The patches of Peyer, in both the small and the large intestine, are elevated, swollen, and pale. They present a reticulated aspect in consequence of the greater swelling of the lymphatic follicles than of the intervening mucous membrane. The heart is filled with blood, the right ventricle being especially distended. The blood is fluid; or soft, dark clots may appear. Neither the kidneys nor the lungs show especial alteration. The spleen is slightly swollen and softened, the liver large, soft, and yellow in color.

The animals that receive a smaller dose and live longer, say from twenty to twenty-six hours, show more pronounced lesions. All the superficial lymphatic glands are greatly swollen and dark in color. The spleen is often much enlarged, tense, and deep purplish-red in color. The kidneys are congested; sometimes the adrenals also. The mesenteric glands are much swollen, edematous and hemorrhagic. The peritoneal cavity often contains bloody fluid, and there are many subserous hemorrhages into the peritoneal layer of the intestines and mesentery. In some cases there are so many hemorrhages into the omentum that the picture presented reminds one of snake-poisoning. The intestines are distended with semi-fluid, glutinous contents, which often show streaks of blood. The mucous membrane of the intestines is congested, and here and there small hemorrhages are observed; the latter correspond at times with dilated bloodvessels in the serosa filled with dark, clotted blood. Peyer's patches present the most striking lesions, and are uniformly swollen and congested. The swelling is apparent at once through the serosa upon opening the peritoneal cavity and examining the intestines, and the glands often reach such a size that they project into the lumen of the intestine for a distance of two millimeters. At times small points of hemorrhage occur in and around the swollen patches, which always present a reticulated surface. In the stomach ulcers are sometimes found. The liver is dark in color, often much congested, and presents to the naked eye foci of yellowish or yellowish-white color, which at times are surrounded by hemorrhagic zones. A few of the inoculated animals were pregnant, and in these there were without exception hemorrhages into the fetal sacs.

The microscopic changes are well marked. In the lymph-glands hemorrhages are commonly present, and the vessels are greatly dilated and packed with red blood-corpuscles. Many of the lymphatic elements are necrotic; cells with fragmented nuclei are common, and this fragmentation is often extensive. Intermingled with the foci of fragmentation are numerous karyokinetic figures. The lymphatic apparatus of the intestines shows in an analogous manner the destructive influence of the poison, but in this situation the cell-death is much more extensive, and the swelling of the follicles is clearly due in part to an increase in number of lymphoid elements. Nuclear figures are found in considerable numbers. In the intestines the destructive process is not limited to the lymphatic elements in the follicles, but those in the villi suffer extensively, and the epithelial elements are as little spared. Fragmentation and necrosis with rapid cell-multiplication by karyokinesis are present here also. The spleen shows changes similar to the lymph-glands, and these are localized in part in the Malpighian bodies.

The liver presents in many respects the most interesting changes, and a variety of forms of cell-death are met with in this organ. In the capillaries of the liver, which are greatly dilated, the endothelial cells are sometimes fragmented and necrotic, and the leukocytes suffer a similar change. But in the liver-cells themselves the process reaches its height. The yellowish and yellow-white areas visible to the naked eye correspond to foci of coagulation-necrosis of liver-cells. The liver-cells in these areas are still preserved in some instances, but they are hyaline in appearance and devoid of nuclei. At times the nuclei can still be made out in the form of fragments. In other foci the cells are much altered in appearance and staining properties, and the nuclei have undergone another form of necrosis. They have not fragmented, but have died as a whole, becoming paler and paler until they finally fail to stain, with apparently a synchronous alteration in the cell-protoplasm. Still other cells have given up most of their protoplasmic material and appear as almost empty vesicles, with here and there a trace of protoplasm. Again, a group of cells will be converted into a reticulated substance suggesting fibrin; and, indeed, these foci of necrotic cells often give a reaction with Weigert's fibrin-stain, while the remainder of the tissue does not retain the dye.

These foci of necrosis are often surrounded by large quantities of nuclear detritus—to such an extent, indeed, as to exclude the possibility of its having been derived altogether from the tissue-nuclei. Some of the detritus must have come from emigrated cells, attracted, as we now know commonly happens, to these necrotic foci,

where they suffer the same fate as the tissue-elements. An interesting feature was noticed in connection with the lymphatics in the interlobular spaces of the liver. They were at times choked with nuclear detritus. Manifestly such an amount of nuclear material could not come from the cells lining the lymphatics, nor from the cells of the lymph. There is only one interpretation possible of this appearance: it represents the nuclear detritus of the tissues and emigrated cells which had been swept by the lymph-vessels into the current. To accomplish this it is probable that an increased lymph-current is necessary.

That in the short space of time—about twenty-four hours—rapid cell-proliferation occurs in the lymph-glands we have adequate evidence, and we also have reason to believe that the same thing occurs in the liver. Around a focus of necrosis, about 1 mm. in diameter, in the periphery of which the capillaries were greatly dilated and literally choked with nuelear fragments, there were evidences of cellular proliferation in the rapid multiplication of the liver-cells, forming at times actual giant-cells.

The studies of Podwyssozki[1] have shown that in rabbits, after injury to the liver, cell-division by karyokinesis has already begun on the second day, and by that time the various stages of nuclear division are present. He also observed on one occasion liver-cells with colossal dividing nuclei, in which no indication of division of the cell-bodies could be made out; from these he believed that giant-cells were formed.

That the liver of rabbits under certain circumstances possesses marked capacity for regeneration has been shown by the experiments of Ponfick, who, after removing large portions of the organ, found that compensatory hypertrophy of the remaining parts took place.

In this description I have had nothing to say of the alterations of the blood described by Kobert. The thrombi of red blood-corpuscles which he found were also met with in my specimens. But they cannot, I think, be regarded as playing an essential part in the production of the lesions.

When we attempt to explain the phenomena that we have just described, great difficulties are at once encountered. There are, as will be readily admitted, several questions of no small interest involved. For example, what determines the localization of the activity of the poisonous agent to such a large extent upon certain structures? Why do the lymphatic elements everywhere suffer so disproportionately? Are there in the body special tissues whose function it is to destroy, render innocuous or eliminate the injurious substances? And as regards the lesions in the intestinal tract, is it not a matter of indifference whether we introduce the poisonous agent into the blood, by the stomach, or subcutaneously?

Moreover how are we to account for the selection (for such it seems to be) of certain groups of cells on which the greatest stress of the poison is exerted? Shall we be obliged to fall back upon an hypothesis with which we are familiar enough in form, but as far as ever from understanding? I refer to the assumption of a difference of resistance of certain cell-groups of an organ, in consequence of which they fall an easy prey to the poisons which other cells can resist. Or, again, do the areas of necrosis, as has also been suggested, represent foci of especial enzyme-activity, points at which the poison increases, with the result finally of causing the death of the animal, and the lesion described?

These are fundamental questions and doubtless not all to be answered at the present time. But we have certain facts in our possession, derived from experiments, which may aid us in the solution of some of these problems.

Koeppe,[1] working in Ludwig's laboratory, and proceeding on the basis that the lymph flowing into a lymph-gland is poorer in cells than the outflowing lymph, supposed that if the lymph-entrance and lymph-exit were both closed an increase in the size of the gland would take place. He accordingly ligated the afferent and efferent lymph-vessels of one of the cervical lymphatic glands of the dog, and examined the gland, comparing it with its fellow of the other side. To his entire amazement, he found that after two weeks the gland operated upon was much smaller than its fellow, and showed upon microscopic examination fewer mitotic figures. The interpretation of this experiment seems clear: the lymph is the normal excitant of the lymph-gland, and upon its presence depends the production of lymph-corpuscles within the gland. This conclusion is made the more probable by the further observations of Koeppe, that the arterial blood supplied to the gland, so far from being an aid, is a hindrance to the multiplication of the lymph-corpuscles.

From his experiments on lymph-formation, Heidenhain believed that he had proved that the separation of lymph from the blood does not depend upon a process of filtration, but is to be regarded as due to a secretory activity of the cells lining the capillaries. According to him a number of substances are capable of so acting on the capillary walls in the dog as to cause an elimination of an increased quantity of lymph, amounting often to several times the usual amount as measured by the outflow from the thoracic duct. Among the most active agents are the enzymes, derived from the salivary, pancreatic, and gastric secretions. Although Heidenhain[2] considered that his experiments proved that the increased lymph-flow is quite independent of the blood-pressure, yet Starling[3] has just shown that in a number of his experiments there was an increased capillary pressure in the liver, whence a large part of the lymph was derived, and it will be recalled that in the liver in our experimental animals the capillaries are much dilated, often compressing the rows of liver-cells.

These facts are, I think, very suggestive. On the one hand we have learned that the lymph is an excitant of the lymphatic glands, and on its presence depends the formation of lymphoid cells, and, on the other hand, it has been demonstrated that certain ferments may act as the cause of an increased lymph-flow. It is pertinent, I think, since the histologic evidence that an increased

flow was actually induced by these enzyme-like bodies is before us, to inquire whether or not the rapid increase in the lymphatic elements can in part be attributed to this cause.

The variations in the circulation of the blood in the organs must be considered as bearing on the production of such focally distributed lesions as are here described. That the circulation is not equal in all parts of an organ at all times is indicated by observations upon living animals, and the capillary circulation especially is subject to wide variation.

I would ask a consideration of the effect this difference may have in bringing about such focal effects as we have encountered in the liver. We have seen that the action of the poisonous agent is exerted in part upon the capillary walls. The necrosis, fragmentation and regeneration of endothelium indicate this. I would also point out that the injury to the capillary wall is nowhere so great as in the areas in which the necrosis is found. This fact suggests the possibility that, in certain capillaries in which the circulation was much diminished in rapidity or was temporarily at a standstill at the time when the irritant acted with the greatest intensity, such damage was done the capillary wall that a freer transudation took place into the tissues than elsewhere, resulting in the destruction of cell-groups; and Cohnheim[1] has shown that the lymph will be more concentrated the greater the permeability of the vessel-wall.

I have already alluded to the fact that in such areas there is an abnormal accumulation of leukocytes. The general blood contains an increased number of these cells, but there are relatively many more in the areas of necrosis.

We now know, thanks to the researches of Stahl,[2] Pfeffer,[3] Leber,[4] Buchner,[5] and others,[6] that certain stimuli of a chemic nature attract and repel these as well as other cells. In undergoing necrosis, certain chemic changes take place in the tissues, through which the leukocytes are attracted to them, but some bacterial products are still more positively chemotactic than are those substances derived from cells. In order that this attraction shall be exerted, Pfeffer discovered for the sperm-threads of ferns that the attracting substance could not be equally diffused throughout the fluid, but must exist in a greater concentration in one part than in others. There is then an immediate movement toward the areas of concentration. It seems plausible at least that the poison which is conceived to be in greater concentration in the areas of necrosis exerts a positively attractive influence upon the leukocytes. To test this point the following experiment was made.

Capillary tubes were filled with a solution of ricin in normal salt-solution of varying strength, 1 to 100,000, 1 to 200,000, 1 to 500,000, 1 to 1,000,000, and introduced beneath the skin of rabbits. Control-tubes of sterilized physiologic salt-solution were also introduced. After twenty hours the ricin-solution of 1 to 100,000 proved to be strongly chemotactic, the open end of the tube being plugged by a thrombus of leukocytes, fibrin, and granular material. The weaker solutions exhibited positive chemotactic properties directly in proportion to the concentration. Only a few leukocytes were found in the tubes containing simple salt-solution.

There remains one other class of ricin-cases, those of chronic character. These are more difficult to obtain, and very small doses must therefore be employed. I give a typical case.

On November 9th, a guinea-pig, weighing 600 grams, received 1.5 c.c. of a 1 to 200,000 solution of ricin, subcutaneously. There was considerable local reaction; a hard node appeared over the site of injection, which, however, gradually disappeared. The animal lost weight for several days, but ten days subsequently to the inoculation had about regained the loss. On December 11th, seeming to have recovered, it was allowed to run about freely, and was often noticed to eat voraciously. Notwithstanding this fact, it grew more and more emaciated until December 29th, when its death occurred. At this time its weight was 270 grams.

At the autopsy the emaciation was extreme. The lymphatic glands were not enlarged; the spleen was small and dark, the liver dark. The intestines contained semi-fluid, mucus-like and turbid contents, and the mucous membrane was much attenuated. Cultures made from the organs were entirely negative.

This picture is strikingly different from that observed in the other class of cases, and presents the features of a profound disturbance of nutrition. The microscopic examination of the tissues showed by the amount of iron-containing pigment in the spleen and liver that great hemolysis had taken place. But of especial interest is the occurrence of atrophic patches in the kidneys.

Up to the present time we have considered the histologic lesions that are produced by the vegetable toxic proteids. I would now ask attention to those caused by toxic agents of animal origin.

Thus far my studies have been confined to the action of the blood-serum of man and dogs upon rabbits. We know from the experience of Landois,[1] Ponfick,[2] Daremberg,[3] Buchner,[4] Carter,[5] and others, that the immediate effect of the injection of serum is the destruc- of the red and colorless blood-corpuscles. The animals, as often happens, may succumb immediately, in consequence of thrombosis of the right side of the heart and pulmonary artery, the respiratory function ceasing before the heart's action. Not uncommonly the animals experience less severe effects, and after a variable period of depression, increased frequency of respiration, weakness and hemoglobinuria, apparently recover.

I have found dog's serum strongly globulicidal for rabbits. This statement is based upon the common occurrence of hemoglobinuria that lasted from one to two days, as well as upon actual counts of the number

of red blood-corpuscles. Doses of 1.5 per cent. of the body-weight were usually fatal to rabbits. In these cases death occurred either immediately or after ten or twelve hours. Quantities of one per cent. of the body-weight caused profound disturbances, including hemoglobinuria and albuminuria, and less commonly anuria, and in a few instances immediate death. Some of these animals survived several days or weeks, and some even appeared to recover. They were, however, as we have seen, more susceptible to subsequent inoculations.

When death follows at once upon, or soon after the inoculations, it is usual to find thrombi in the right side of the heart, which may extend into the pulmonary artery and its main branches. The rapid breaking up of the corpuscles liberates the fibrin-ferment, with consecutive coagulation of the blood in the vessels. The experiments of Naunyn[1] have shown that the red corpuscles yield the necessary ferment, and those of Schmidt and others that the white corpuscles, which are likewise destroyed by the foreign serum, are especially rich in this substance.

There are cases, however, in which great destruction of corpuscles has occurred, but in which coagulation has not ensued, and, indeed, under these circumstances the coagulability of the blood is diminished. We owe to the researches of Pekelharing,[2] Wooldridge,[3] Löwit,[4] Schmidt,[5] and others[6] a partial understanding of this difference. It will not be possible for me to enter into the details of this matter here; it will suffice to state that much will depend upon the capacity of the organism to dispose of the liberated fibrin-factors and upon their behavior with regard to the calcium-salts of the plasma.

The cases already alluded to, in which the death of the animal is delayed for a time, are of especial interest, as they show certain well-marked lesions. While the observations that I have made are more complete as regards the action of the serum of the dog upon rabbits, the serum derived from human beings apparently acts in much the same way. Permit me to say that these lesions resemble, but are not identical with, those described in connection with the toxalbumins of diphtheria, ricin, and abrin.

The tissues of animals dead of serum-poisoning which I have so far studied consist of the spleen, liver, kidneys, and lymph-glands. In the acute cases the spleen shows a tolerably rich fragmentation of nuclei situated especially in the Malpighian bodies; the liver contains foci of necrosis of liver-cells, and the renal epithelium is degenerated and many methemoglobin-casts block the kidney-tubules.

Of especial interest is an animal that died on the thirteenth day in which very extensive lesions were found:

A rabbit received on December 25, 1893, 1 per cent. of dog's serum, twenty-four hours old, intra-venously, and was dead in twenty minutes after completion of the inoculation. A second rabbit weighing 1200 grams received ½ of 1 per cent. of serum from the same source. There were no immediate perceptible effects. After the lapse of thirty minutes the expressed urine contained hemoglobin-casts. For some days following the inoculation the animal appeared to be in perfect health, but about the seventh day it began to lose in weight, grew perceptibly weaker from day to day, and died on January 6, 1894.

The autopsy showed great emaciation. The peritoneum contained an excess of fluid; the axillary lymph-glands were enlarged; the intestinal lymphatic apparatus was apparently normal. The liver, which was firm in consistence, was roughened externally and dark in color. The kidneys appeared small; their capsules were not adherent, but their surface was granular. In the spleen, which was enlarged, were a number of white wedge-shaped areas, the bases at the capsule, and quite firm in consistence. Attached to the chordæ tendineæ of the tricuspid valve was a calcified thrombus as large as a split-pea. The urine contained albumin and tube-casts.

The microscopic changes were those of chronic interstitial processes in the liver and kidney. In the latter the tubules were in places atrophied and surrounded by a new growth of connective tissue; in other places the tubules were dilated and the epithelium lining then degenerated; but it was in the liver that the pathologic alterations could best be studied. The chronic changes were well-marked here also, and were such an accurate reproduction of cirrhosis in human beings that a separate description seems superfluous. Areas of newly formed and forming connective tissue, proceeding from the portal spaces and also from the capsule, were irregularly distributed throughout the organ; newly formed bile-ducts were numerous; but what was of especial moment was the association with this of another process, viz., acute degenerative changes in the liver-substance, which were often distinctly the starting-places of the sclerotic process.

In rabbits that died at a somewhat earlier period, after five or six days, I have not infrequently found coagulation-necrosis of liver-cells. To these areas leukocytes are not attracted in such numbers as in cases of diphtheria or poisoning with abrin or ricin; and in keeping with this difference I have found that capillary tubes containing dog's serum, when introduced beneath the skin of rabbits and removed after twenty-six hours, showed very slight positive chemotaxis only.

It is possible in the chronic cases to follow the progress of the pathologic process. The degenerative changes and the new growth of connective tissue can be studied side by side. There is necrosis and disintegration of liver-cells, emigration of leukocytes and growth of connective tissue. The new tissue comes both from the surface-capsule and from the inter-lobular connective tissue, but not exclusively from these. Independent new-formations in the midst of the lobule occur, just as there are independent foci of necrosis in this situation. Here and there, where the connective tissue is advancing, the fast disappearing remains of necrotic cells can be seen; but where the sclerotic tissue is already well developed and new bile-ducts are well formed, this is not always possible. Finally, in the spleen, the white nodules resembling infarcts are masses of fibrous tissue.

The changes found in the organs in cases of serum-

poisoning are, if I mistake not, of no slight importance. They indicate that it is necessary to enlarge our views of the damage that serum is capable of doing, a damage not limited to the corpuscular elements of the blood, for the tissue-cells are not indifferent to its action.

In the end the differences in the action upon the blood and tissues of the toxic agents discussed are not so great as their correspondences—a fact that emphasizes their chemic similarity. These substances so affect the tissue-elements as to cause degeneration and death, and their effects are followed by reparative processes that do not restore the integrity of the tissues. The relation that Weigert[1] several years ago maintained between parenchymatous degeneration and interstitial tissue-proliferation in the kidney, and which Ackermann[2] urged for the liver in chronic phosphorus-poisoning in rabbits, I have been able to follow in the cases mentioned in both organs, although most satisfactory in the liver.

Moreover, the chronic lesions, such as we have just studied, seem to be open to us for experimental study. Heretofore we have had to content ourselves with the production of degenerative changes, and have been excluded from imitating by experiments on lower animals the chronic proliferative processes in the internal organs of man.

In conclusion, the study of the tissue-changes that I have had the privilege of bringing before you has brought us from the consideration of acute degenerative changes of a focal character due to soluble poisons to the realization of the probability of their playing an important part in the production of chronic interstitial changes in animals, which find in cirrhosis of the liver and chronic nephritis analogies in human beings.

CLINICAL MEMORANDA.

CEREBRAL PALSY OF CHILDHOOD FOLLOWING DIPHTHERIA.[3]

By CASPAR W. SHARPLES, M.D.,
of Seattle, Wash.

Comparatively recently a group of cases has been recognized as the cerebral palsies of childhood, having definite relations one to another and separate from ordinary infantile palsy. The condition often makes its appearance as a sequel of some acute infectious disease, such as scarlet fever, measles, etc. Most of the cases offered for study are those of months' or years' duration, and when seen they present as the one characteristic a spastic state of the muscles of the affected side, associated, if of long standing, with a decrease in the size and length of the limbs. Many present various evidences of cerebral disturbance, as epilepsy, idiocy, etc. The occurrence of cases of this class of hemiplegia after diphtheria is rare. Among one hundred and sixty cases of spastic hemiplegia tabulated by Wallenberg only three cases followed diphtheria or croup; nine followed measles; thirteen, scarlet fever; and six, epidemic cerebro-spinal meningitis. Of Osler's one hundred and twenty cases none was reported to be due to diphtheria; and if I recall correctly none of the cases tabulated by Dr. Sarah McNutt, in her paper on "Spastic Hemiplegia," followed diphtheria.

To say just what has taken place in the brain in these cases is difficult, for autopsies in cases of recent date are rare, because most of them survive the immediate dangers of the primary condition, and new processes obliterate to some extent the original state of affairs. Sclerosis, then, is the most common condition found, with porencephalon, simple cysts, and softening as rarer conditions.

A recent German journal contained the report of a case very much like the present one. About six days after the diphtheric membrane had disappeared the boy suddenly became comatose; on emanating from this condition he was found completely paralyzed on his right side, and was also aphasic. After the lapse of five months the aphasia had to a great degree disappeared and motion was returning in the arm and leg, although he still presented the hemiplegic gait. This is the only case of the kind of which I have seen any record.

I venture to report this case on account of the infrequent occurrence of similar ones. I am indebted to Dr. L. R. Dawson for the privilege of seeing the case and reporting it.

J. C., a boy, thirteen years old, had an attack of diphtheria a short time after his father recovered from an attack of erysipelas of the face following a scratch from a fall. Before the membrane had disappeared, and although he was apparently doing nicely, his heart began to be irregular and rapid. About midnight, December 4, 1893, he was suddenly paralyzed upon the entire right side. Coma was not deep or long, for in a half-hour the boy realized what was going on around him. No convulsions accompanied the onset. Preceding the attack, during the evening, the child frequently cried out, making a peculiar sort of noise. This was continued during the day and especially if he was disturbed in any way.

I first saw the patient twenty-four hours after the onset of the trouble. His mental state was improving. The right side of the body was the seat of tremors that shook the entire body. These would last off and on for a half-hour and would recur at irregular intervals during the day. The skin was hypersensitive. Touching the leg would cause the boy to cry out as if in pain. The arm did not present these phenomena to the same extent as did the leg. The tendon-reflexes at the time were absent.

Speech was wanting, although the child appeared to understand what was said to him, and was able to make his displeasure known. His heart was behaving very poorly; its action was tumultuous, irregular, and weak, so that death would not have been a surprise at any time, and it so continued for three or four days, gradually coming down to normal. No heart-murmur was detected. The urinary secretion was scant and passed infrequently. The bowels only moved after the administration of drugs or if injections were used.

This report is made four months after the onset. There has gradually been a return of the power of speech and of motion. Motion began to return in about five weeks, when the boy made an effort to walk with assistance, and now he gets along by himself very nicely, with the ordinary hemiplegic gait. For a time, to obtain any motion in the right hand and arm, he had to use the left

[1] Volkmann's Sammlung klin. Vorträge, 1879, Nos. 162, 163.

[2] Virchow's Archiv, 1889, Bd. 115.

[3] Read at the annual meeting of the State Medical Society of Washington, May 2 and 3, 1894.

to the same purpose, when the right would coördinate; yet the use of the left arm did not always excite motion in the right. Two weeks ago when he attempted to squeeze my hand, he made a very strong left-handed contraction and a scarcely perceptible right-handed one. To-day he could raise his arm a short distance from his body, and could extend the little and ring fingers so that they were nearly straight.

Athetosis has not been present, though at times while moving the left arm the fingers of the right would assume a position approaching athetosis. This now has disappeared.

As is common in ordinary hemiplegia and as is characteristic of hemiplegia in children, the tendon-reflexes have been increased. They are more marked in the leg than in the arm. Ankle-clonus could not be elicited. The skin-reflexes are still exaggerated. Electric examination does not show any reaction of degeneration. In both the arm and the leg the galvanic current causes a contraction of the limb—acting, I would say, through the skin, and producing an exaggerated skin-reflex.

The size of the limb has decreased, as shown by the following measurements: The right calf measures 10.6 inches; the left calf 10.9 inches; the right thigh 13.1 inches; the left thigh 13.5 inches; the right forearm 6.5 inches; the left forearm 7 inches; the right biceps 7 inches; the left biceps 7.5 inches.

The aphasic condition has improved and no doubt will continue to improve until the boy can talk fairly well. At first he could not say a word. After commencing to talk he would use the wrong word. "Yes" was the first thing he could say. After naming an object incorrectly, he would recognize his mistake, but could not correct it, and often could not repeat what he was told. He now occasionally joins a couple of words coherently. To-day he said "Papa—Sharples," meaning that his father had brought him to the office. Occasionally he says something "hurts there."

So far there has been no mental deterioration, unless it be that the boy is more irritable than he was. He adds, multiplies, etc., as well as ever.

For a month the galvanic current has been applied, and within this period he has made more rapid improvement than at any previous time; yet I would not attribute too much to electricity.

There are two other points of interest in the family. His mother had paralysis of the palate, so that deglutition was uncertain and speech poor. The sister, a couple of years older than the boy, who was the last of the family afflicted, and had had her feelings much worked upon by her brother's paralysis, had two hysterical seizures in which right hemiplegia was quite well simulated.

It is a matter of common occurrence to find palsies of different types or locations after an attack of diphtheria. These palsies depend on certain local conditions, the most common being a neuritis involving individual nerves, though separate nerves situated in different parts of the body may be affected at the same time.

The motor nerves show more profound changes than the sensory ones. Yet we are too liable in looking at a case of post-diphtheric palsy to consider it a peripheral neuritis and to look no deeper.

In any lesion of the peripheral portion of a nerve, degenerative changes travel up as well as down, and if they enter the cord they do so by means of the posterior roots. In a few cases of post-diphtheric palsy the degenerative changes have been found in the anterior roots, indicating beyond a doubt that the lesion has destroyed some of the cells of the gray matter of the cord. One observer has found in the substance of the cord colonies of the same germs as exist in the membrane of diphtheria, and the nerve-sheaths have also been found infiltrated with the same germs. In one case in which the latter condition existed, the brain contained a number of infarcts.

These facts have been mentioned to show that if diphtheria can be productive of such conditions in the nerves, and more especially in the cord, it would be only reasonable to attribute a similar causative relation to diphtheria followed by cerebral lesions. Yet it may be justly said that if this were the fact cerebral lesions would be more common after diphtheria than they are. It may be true that diphtheria did not have any more relation to this condition in the case here reported than any other septic or infectious process would have had; and the reason for this would appear the stronger when it is considered that the essentially diphtheric palsies are peripheral and due to an inflammation of the nerves.

As to the question of diagnosis, there is no doubt now, nor was there at any time a reasonable one. The case differed from common infantile palsy in the manner of onset, being sudden and immediately complete, while the other develops gradually and progressively. The time of occurrence, in relation to the attack of diphtheria, was as would be expected for both conditions. The loss of consciousness was complete for only a short time, while if there had been an extensive hemorrhage into the brain-substance, this loss would have lasted longer. It was such as comes on from cerebral embolism. Some observer has stated that these cases of hemiplegia may be caused by colonies of germs plugging a vessel. Aphasia indicated the central origin of the lesion, yet if there had been a neuritis of the inferior laryngeal nerves alone, there would have been aphonia. The subsequent state of ataxic aphasia offsets the possibility of any local condition.

All reflexes were gone at first on the affected side, but have returned. For diagnostic purposes at the time of onset they were of no aid. In diphtheric palsy they only return. In our case they have returned and have also become exaggerated. This change indicates the central origin. The tremor and involuntary movements of the right side indicated that some central irritation was taking place.

In one case in which an autopsy was made soon after the hemiplegia, a very small hemorrhage was found. Porencephalon is attributed to plugging of a cerebral vessel, and as so many cases of cerebral palsy of childhood show porencephalon, the embolic origin of these cases must be quite frequent.

One more point I want to mention, and that is that erysipelas occurred in the house just preceding these cases of diphtheria. The same causes evidently act to produce these two conditions, as they are often found associated in the same houses.

Note.—This boy has materially improved in speech and motion, and the size of his limbs has also increased.

A CASE OF ELECTRIC SHOCK OF ONE THOUSAND VOLTS; INSENSIBILITY OF PATIENT TO PAIN; RECOVERY.

BY P. S. DONNELLAN, M.D., L.R.C.S.,
OF PHILADELPHIA;
VISITING PHYSICIAN TO ST. MARY'S HOSPITAL.

I AM indebted to the courtesy of my colleague, Dr. W. M. L. Coplin, for the privilege of reporting the following case.

On the 20th of April, 1894, J. R., aged forty-four years, while engaged in repairing broken wires for the Bell Telephone Company, grasped the ends of a wire that had crossed an electric light wire, conveying one thousand volts. He received the full force of the current through his body, and was immediately rendered unconscious. He was thrown violently to the ground, and could not be released until the current was broken by a fellow-lineman, who cut the wires apart with a hatchet.

The man was brought to St. Mary's Hospital at 11 A.M., within half an hour of the accident, and I saw him a few minutes after his admission. He was in profound coma, with pupils widely dilated and irresponsive to light, breathing stertorous, face pale and bathed in perspiration. About ten minutes later he vomited, and then became wildly delirious, so that it required the combined efforts of three men to keep him in bed. He moaned and cried incoherently, and tonic and clonic convulsions of a severe type succeeded each other with great rapidity. At this time we were unable to take his temperature on account of his extreme restlessness, but to the hand it appeared about normal. His respirations now lost their stertorous character, and became more of the Cheyne-Stokes variety, averaging about ten per minute for two hours after his admission. The pulse was 80 per minute, of high tension.

At 11.40 A.M. the man was given morphin, gr. $\frac{1}{4}$, by hypodermatic injection; and as the delirium and convulsions did not abate, the injection was repeated at 12.10, and soon afterward he gradually quieted down. About 1.30 P.M., as his respirations were alarmingly feeble, he was given strychnin, gr. $\frac{1}{30}$, by hypodermatic injection with excellent effect. At 2 P.M. he fell into an apparently normal sleep, from which he awoke four hours later, conscious, but slightly dazed, and feeling, as he expressed it, "tired and sore all over." On my visit to the hospital next morning I found that he had slept well during the night; his temperature was 98.8°, his pulse 72, his respiration 18. He complained of pain from a number of severe burns that he received during his contact with the wire. These burns were distributed irregularly in lines over the back, arms and legs, and evidently were caused by the intensity of the current, as the clothing which covered the affected areas showed no signs of having been scorched.

On questioning the patient as to the nature of the accident, he remembered perfectly all of the incidents of his morning's work up to the time when he grasped the wire that conveyed the shock through his body. After that moment he had not the slightest knowledge of what had occurred, and did not suffer the least pain until he awoke at 6 P. M., as already stated, to find himself in bed in the hospital.

The subsequent history of the case was uneventful. The patient made an excellent recovery.

In view of the employment of electricity by the authorities of certain States for the purpose of putting condemned criminals to death, the facts of the case related are of interest. Dr. J. W. Brown[1] has published the history of an electrocution that took place at the prison at Auburn, N. Y., in which the condemned man received a voltage of 1260 through his body for fifty-six seconds, and, being apparently dead, he was released from the straps. To the horror of those present, he gasped for breath and began to revive. He was placed again in the chair, but the current would not work, so that he was removed to the hospital, and developed a train of symptoms precisely similar to those observed in the case that I have reported. A second contact an hour and fifteen minutes later resulted in death in forty seconds. The case attracted great attention at the time, from the supposed agony of the condemned man, who was regarded by the newspapers as a hero on account of his sufferings. According to the statement of our patient, he was absolutely insensible to pain from the instant he received the shock: even the actual discharge of the current caused him no suffering; and were it not for the burning of his skin, he would not have been aware that he had met with an accident.

While it is to be regretted that the public is greatly exposed to accident from contact with currents of high tension on account of the almost universal employment of electricity as a motive and lighting power in our large cities, it seems to me that, so long as capital punishment has to be enforced as a legal penalty, the electric current, properly applied and of sufficiently high tension, is the most humane agent yet devised for putting condemned criminals to death.

THE CAUSE OF THE FEVER IN THE INFECTIOUS DISEASES.

ATTENTION has more than once been recently directed to the laboratory of PROFESSOR TIZZONI, of Bologna, through the reports of the careful chemic and physiologic researches that have issued from it. One of the latest and most important of these deals with the origin of the fever present in the infectious diseases. The article is by CENTANNI,[1] and the conclusions at which he arrives cannot, when they have become generally known, fail to excite wide interest and to stimulate further investigation in neighboring fields.

CENTANNI'S results, briefly stated, are these: The febrile phenomena occurring in the course of bacterial infection are the consequence of a general intoxication of the patient with a poison, to which he gives the name *pyrotoxina bacterica*. This substance is formed within the bodies of the bacteria themselves, and is entirely distinct from such bacterial poisons as the ptomaïns, enzymes, and toxalbumins. The pyrogenic substance is present in approximately constant amounts in all bacteria, both pathogenic and non-pathogenic, and, though found in the different bacterial species, appears to have in all the same chemic and physiologic properties.

In the preparation of the pyrotoxin, cultures of bacteria several weeks old were first heated and afterward boiled; the dead bacteria were then filtered out, the filtrate concentrated and treated with alcohol, the resulting precipitate being afterward dissolved in distilled water and freed from albuminates by dialysis. By a repetition of the alcoholic precipitation the substance was finally obtained in a comparatively pure state and dried over sulphuric acid.

The pyrotoxin thus prepared is a grayish-white amorphous powder, soluble in water and in glycerin, but insoluble in strong alcohol, ether, or chloroform. It is not injured at the temperature of boiling water. It is very hygroscopic, rapidly becoming fluid when exposed to the air. By the application of various chemic tests it has been shown not to be an albuminoid substance; it differs from the bacterial proteins described by BUCHNER and the nucleins of GAMALEIA, and cannot be classed with the ptomaïns or enzymes. In fact, it is a product that does not fall in any of the groups in which the chemic substances derived from bacteria are at the present time ordinarily arranged.

When injected into animals (rabbits) the pyrotoxin induces all the typical phenomena of a febrile reaction, just as is seen when bacteria themselves, or simple extracts from them, are thus employed. The height of the temperature is directly proportionate to the quantity of the poison administered. The older the cultures used the more intense is the pyrexia, and the steeper are the ascending and descending limbs of the temperature-curve. Marked emaciation, often leading to fatal marasmus, is a characteristic effect of the injections. Serious disturbances of digestion are produced, diarrhea occurs regularly, and loss of appetite is equally constant. Acceleration of the pulse and respiration is frequently associated with marked dyspnea. There is a very evident general weakness, so that the animal staggers when it attempts to rise. At autopsy the intestine is found filled with fluid feces: the vessels are hyperemic; there are signs of excessive secretion of mucus, and Peyer's patches are markedly swollen. The local phenomena at the site of injection vary: if absorption be speedy there may be only edema and hyperemia; if absorption be delayed, by en-

[1] Centanni, E.: Untersuchungen über das Infektionsfieber. Das Fiebergift der Bakterien. Deutsche med. Wochenschr., 1894, Nos. 7 and 8.

closing the pyrotoxin in sterile glass tubes, suppuration may be set up.

CENTANNI separated the pyrotoxin from a large number of varieties of bacteria, both pathogenic and non-pathogenic, and, as we have said, as far as he was able to determine, the products obtained were in all cases, chemically and physiologically, essentially the same. This observation, he thinks, should not occasion surprise, but is rather what should have been expected, as there is plenty of evidence in the literature to prove that cultures of saprophytic bacteria, when injected in sufficient quantity, are capable of causing toxic phenomena, and even death of the animal; besides, the examples of sapremia in human beings produced by non-pathogenic bacteria are so well known that they need only be mentioned to be immediately recalled. As a matter of fact, the earliest studies of fever of bacterial origin, those of TRAUBE and GSCHEIDLEN, were conducted with the putrefactive bacteria, and the pyrogenin of ZUNTZ and ARONSOHN was separated from cultures of the hay-bacillus.

The weakening of the virulence of pathogenic bacteria does not apparently lessen the amount of pyrotoxin in the bacterial bodies. In spore-bearing cultures the extracts are less active than those made from cultures of the same organisms free from spores. CENTANNI is therefore of the opinion that the pyrogenic substance may be included within the spores, and thus be rendered inactive. The pyrotoxin certainly has its origin in the bodies of the bacteria, and most probably, as he thinks, in the chromatic substance. It is possible, he further suggests, that the extracts from certain bacteria owe their activity in the main to the presence of pyrotoxin, and he puts forward tuberculin as an an example, inasmuch as it has been shown repeatedly that a typical tuberculin-reaction can be evoked in tuberculous animals by the injection of extracts of bacteria of different sorts, even of the non-pathogenic varieties.

Cultures of such organisms as the tetanus-bacillus, the influenza-bacillus, and the diphtheria-bacillus contain, of course, other and more important active principles, but the pyrotoxin is always present along with these. The other substances usually act very quickly and powerfully, and may even lead to a fatal termination before the fever-poison has accumulated in sufficient amount in the organism to make its physiologic action clearly manifest. But when these special powerful poisons are destroyed (by heat in the case of toxalbumins, or by extraction with alcohol in the case of ptomaïns) the cultures, like those of all other bacteria, yield on injection the typical febrile phenomena.

That the results of the investigations just outlined, if confirmed, are significant, not alone as far as the general biology of bacteria is concerned, but also particularly with reference to the practical question of a rational therapy for the fever of infectious diseases, goes without saying. It will be necessary henceforth in pyrexia of bacterial origin to recognize a simple intoxication with a perfectly definite poison worthy of being grouped with the intoxications due to tetanotoxin, to ricin, or to abrin.

Inasmuch as it has been possible in many cases, by means of careful vaccination, to produce in animals immunity to the definite bacterial and other vegetable poisons, so that the serum of the animal rendered immune when injected into another animal is capable of nullifying the poison, or of causing the rapid disappearance of the symptoms even after they have once been set up, CENTANNI hoped that he would be able to prepare an antitoxin for this *pyrotoxina bacterica*, and moreover prophesied that, as the pyrotoxin was the same in all bacteria, when once the antitoxin of the fever-poison of a single bacterium had been found, it would be the antitoxin for all pyrexia of bacterial origin. Since his report was published, a second article (by CENTANNI and BRUSCHETTINI[1]) has appeared, in which some experiments are recorded which permit an *à posteriori* view quite in accord with these *à priori* speculations.

BRUSCHETTINI, while experimenting with the influenza-bacillus, had noticed that animals undergoing vaccination very soon failed to react to strong doses of the vaccine, and that the serum of such an animal would not only prevent infection with the influenza-bacillus, but was also capable of bringing about a rapid and considerable depression of the body-temperature. As CENTANNI'S experiments had proved that the fever-poison of the influenza-bacillus was the same as that of other bacteria, what more likely than that the serum immunizing against this disease should prove just as efficacious in combating the fever called forth by infection with other bacteria. CENTANNI and BRUSCHETTINI therefore set to work to test the question in three ways, studying the effect of antitoxic

[1] Centanni, E., und Bruschettini, A.: Untersuchungen über das Infektionsfieber. Das Antitoxin des Bakterienfiebers. Deutsche med. Wochenschr., 1894, No. 12.

serum (obtained from a sheep rendered immune to influenza) on fevers produced (1) by inoculation of pyrotoxin separated from bacteria, or of sterilized cultures; (2) through injection of living cultures of bacteria that set up local infection; and (3) through injection of some of the bacteria that can cause septicemia in rabbits. Space does not permit of a detailed description of the observations made, although many points of interest are recorded: it must suffice for the present to state that the evidence, as far as the work has gone, goes to support the main point sought to be proved—namely, that the serum of an animal vaccinated against the fever induced by one definite species of bacteria exercises its antitoxic influence also against the infection-fevers caused by the most different varieties of bacteria or their pyrotoxin. The influence of the serum is constant, powerful, and continuous, and the protection lasts for at least some time (in one case for seven days).

All these results are most encouraging, but it must be confessed that the antipyrotoxin has not been isolated in purity, that the experiments have all come from one laboratory, and that they are not as yet very numerous. As the science of bacterial toxicology is much younger than that of bacteriology itself, and as we are only now freeing ourselves from too wide generalizations made in bacteriology, it is, above all things, necessary to guard against hasty conclusions and the acceptance, without mental reservation, of new views until they have been approved and confirmed by a number of workers. Nor is it justifiable, as more than one bitter experience has taught, to transfer the result of animal experiments *ohne weiteres* to the domain of human physiology and pathology. After we have satisfied ourselves of the constancy of the results in animals, numerous trials and observations by competent and trustworthy men in large hospitals must be made before general conclusions are warranted.

EDITORIAL COMMENTS.

The British Medical Association.—Through the fraternal courtesy of the *British Medical Journal* we are in a position to present to-day in an abridged form the Address of the President, the Address on Medicine, and the Address on Surgery, delivered before the sixty-second annual meeting of the British Medical Association just held at Bristol. It is a source of no little gratification to be able to publish simultaneously with our distinguished English cotemporary a partial report of the work of the great medical body of which it is so worthy a representative. We would especially commend to the consideration of educators, surgeons, and the general profession the timely and valuable suggestions offered by Mr. Greig Smith in his charming and interesting Address on Surgery.

A National Bureau of Health.—Having wasted much valuable time, and having kept the country all the while on the ragged edge of uncertainty, it is to be fervently hoped that the present Congress will not adjourn without making a law the bill before it for the creation of a National Bureau of Health. With the threatenings of cholera all over Europe and the actual existence of the disease in many places, and with the further possibility of an invasion of the bubonic plague now playing such havoc in China, the new body might soon be able to demonstrate the justification of its establishment.

Immoral Massage.—The *British Medical Journal* has called attention to a form of immorality which it has discovered is practised in some parts of London under the name of "massage." As a result of this exposure the police authorities have taken the matter in hand, and it is likely that the abuse will thus be repressed. The *Journal* calls attention to the social elements involved in the question of directing massage, and makes a timely criticism of the employment of a masseur in the treatment of women on the one hand and of a masseuse in the treatment of males on the other hand. Massage of the uterus the *Journal* regards with suspicion and dislike and would taboo generally.

Ophthalmia Neonatorum.—The outbreak of an epidemic of ophthalmia neonatorum in the tenement-district of New York City should impress legislators with the urgent necessity of enacting such laws as will tend to prevent, as far as possible, the occurrence of the infection and to check its continuance and extension should any case arise. The cost of the necessary measures would be far less than the pecuniary loss entailed upon the community by the loss of vision and other concomitants following this virulent affection of delicate and important structures.

Quackery in England.—The British Medical Association, through the energetic Chairman of its Parliamentary Bills Committee, Mr. Ernest Hart, is engaged in a laudable attempt to suppress quackery in England, and to this end has undertaken a collective investigation for the purpose of securing data for presentation to Parliament demonstrating the magnitude of the evil.

CORRESPONDENCE.

THE TRICHLORACETIC-ACID TEST FOR THE DETECTION OF SERUM-ALBUMIN IN URINE.

To the Editor of The Medical News,

Sir: In an article entitled "A Serious Fallacy Attending the Employment of Certain Delicate Tests for the Detection of Serum-albumin in the Urine, especially the Trichloracetic-acid Test," in The Medical News

of May 5, 1894, p. 477, Dr. D. D. Stewart speaks of trichloracetic acid as an "absolutely uncertain and even dangerous reagent, so likely is it to mislead."

For the introduction of this test into the United States, Dr. D. Meredith Reese, late assistant resident physician at the Johns Hopkins Hospital, is largely responsible. As his work was practically carried on before my eyes, and as I myself have employed the test mentioned, both at the Johns Hopkins Hospital and in private practice, ever since, the number of my individual observations now exceeding five thousand by far, it may not be altogether out of place to say a few words in reference to this matter.

Let us first of all examine a little into the reasons that led Dr. Stewart to look upon trichloracetic acid as such an "uncertain and even dangerous reagent." The statement appears to be based upon an examination of the urine of 105 young men, all of whom, save one, regarded themselves as in good health at the time. The examinations were made in order to ascertain the frequency of reaction to the more delicate tests for albumin of urine from *normal* individuals. On examination, with but three exceptions, all of the 105 specimens gave an "undoubted" response to the trichloracetic-acid solution; of the remaining 102 *normal* individuals, 20 gave an undoubted serum-albumin reaction to nitric acid by the contact-method, so that we may at once throw out these 23 cases, *i. e.*, 21.6 per cent. The conclusion thrusts itself upon the reader's mind rather forcibly, that the "normal" material was rather unfortunately chosen, one person not considering himself in good health, another having a weak heart, being an overtrained athlete; another having a mitral systolic, and still another an aortic diastolic murmur. In but 2 of the 20 cases in which an "undoubted" serum-albumin reaction was obtained with nitric acid, had a microscopic examination of the urine been made, the result, however, not being stated. Dr. Stewart declares that not one of these cases showed evidence of renal disease, a statement that prompts the question whether the examination of a patient's urine for albumin is *altogether* made for the purpose of establishing the existence or non-existence of *renal* disease. Of a physical examination of the remaining 82 cases, Dr. Stewart furthermore makes no mention, but assumes that because in these the nitric-acid test proved negative (I suppose that this examination was made, although no direct statement in this connection is made), "normally urine contains traces of serum-albumin, or more probably that the response to trichloracetic acid was due to the presence of a body of nucleo-albuminous (or mucinous) character of extra-renal origin." In other words, Dr. Stewart appears to regard the boiling and nitric-acid tests as representing the extreme limits of delicacy for the detection of albumin!

Although it might be argued that, as 19 per cent. of "normal" individuals presented traces of albumin in the urine, recognizable by the nitric-acid test, this latter must also be regarded as "uncertain and even dangerous"—a rather precarious position, however, to take—there remains to be considered the fact that the urine of 82 cases among the 105 reacted in a positive manner to the trichloracetic-acid test, and not to the nitric-acid test (that this has been made, I merely infer, as already pointed out), a reaction that Dr. Stewart refers to the presence of a mucinous body. In Reese's work it is pointed out that "that frequent source of error, urinary mucin, or an extra-renal albuminous body, was not regarded in question." On the most careful perusal of Dr. Stewart's work I confess myself unable to find a single statement or experiment in support of the view that he himself (rather cautiously, it is true) expresses—namely, that the trichloracetic-acid reaction obtained by him is referable "more probably" to the presence of a mucinous body, an inference as to the validity of which he "has no doubt."

Rather interesting, not to say naïve, is the manner in which Reese's 14 cases (not only 11, as Stewart has falsely read) are viewed, in which the nitric-acid test was negative, the trichloracetic-acid test positive, and in which granular, hyaline, and epithelial casts were found. To Dr. Stewart these cases are "of especial interest, as they indicate the frequency of non-albuminuric nephritis!" In support of this view, apparently, he cites the words of Dr. Osler, that "word comes over so constantly from the laboratory—'degenerative changes in the kidneys'—in patients whose urine showed no special alterations." I should like to ask Dr. Stewart whether or not he regards the presence of granular, hyaline, and epithelial casts, as found by Reese, as especial alterations of the urine.

When Dr. Stewart then goes on to state that these observations of Reese's "indicate, beyond a doubt, to my mind that the trichloracetic-acid reaction was but a coincidence, obtainable markedly in as many consecutive healthy subjects," in other words, that the reaction obtained was referable to a mucinous substance, he certainly goes a little too far, and has apparently forgotten our modern standpoint in reference to the significance of tube-casts. On page 159, Part II, of Neubauer and Vogel's *Urinary Analysis*, he may find the following: "As to the significance of tube-casts it must be remembered that these, according to our present knowledge, consist of albumin, which coagulates under the influence of the acid reaction of the urine in the renal parenchyma in a peculiar hyaline manner. They merely represent a solidified portion of the albumin held in solution by the urine; their elimination thus essentially indicates the existence of an albuminuria." That these tube-casts, however, consist of a mucinous substance has, as far as I know, never been demonstrated. I can, therefore, see no reason to assume that the trichloracetic-acid reaction in Reese's cases should be referable to the presence of a mucinous body, when the presence of serum-albumin is already demonstrated by the occurrence of tube-casts.

That the association of casts with the reaction obtained by Reese was furthermore not a coincidence, as Dr. Stewart is pleased to regard it, and "obtainable markedly in as many consecutive healthy individuals," is shown by the fact that in 25 cases of Reese's series *no reaction whatsoever was obtained*. It might be argued, that although casts may be present in urine, a positive though faint albumin-reaction may not necessarily be due to serum-albumin, but, as Dr. Stewart would like to have it, to a mucinous body, as cylindruria has been said to occur in the absence of albuminuria. In antagonism to such an argument I should state that I have frequently observed the presence of hyaline tube-casts in urine

when the nitric-acid test and the boiling test with acetic acid were entirely negative, but in which the trichloracetic-acid reaction furnished a positive result; in other words, I can say that with the employment of trichloracetic acid I have never seen a case of cylindruria *sine* albuminuria, a point that I have repeatedly demonstrated to the gentlemen who participated in my course in urinary analysis at the Johns Hopkins Hospital.

A few examples may not be altogether out of place:

Case I.—Here the urine was light-yellow in color and clear, with a light, flocculent sediment; the reaction was strongly acid, the specific gravity 1020; sugar was absent, the indican moderately increased. There was no reaction on boiling, or with nitric acid; with trichloracetic acid a fine ring was obtained. Microscopically, hyaline and slightly granular casts were found. According to Dr. Stewart, this was a mere coincidence. On physical examination the patient was found to be hemiplegic, the palsy having developed a year before, at the age of fifty-three. There was a high-tension pulse and a ringing aortic second sound. In view of the history of the case and the examination of the patient, it would appear rather dogmatic to regard the positive trichloracetic-acid reaction as a mere coincidence and dependent upon the presence of a mucinous body.

Case II.—In this the urine was of a dark-amber color, and clear, with a light, flocculent sediment; the reaction was markedly acid, the specific gravity 1030; sugar was absent; the indican moderately increased; there was no reaction on boiling, or on applying the nitric-acid test; with trichloracetic acid, however, a trace of albumin was noted; microscopically, hyaline and granular casts were found. Clinically, the case was one of uremia, with convulsions.

Case III.—The urine was of a light-amber color, clear and acid, with a light, flocculent sediment and a specific gravity of 1017. A trace of albumin, not demonstrable on boiling or with nitric acid, was noted with trichloracetic acid, together with the presence of hyaline and granular casts. The patient was seventy years old, with well-marked arterio-sclerosis. Death took place a few months later in uremic coma. Shortly before death a large amount of albumin was demonstrated on boiling and with nitric acid.

Case IV.—The urine was of a light-amber color, clear and acid, with a light, flocculent sediment and a specific gravity of 1021. A trace of albumin was demonstrated with trichloracetic acid, although the reaction on boiling and with nitric acid was negative. There were also hyaline casts. The patient died two weeks later. At the autopsy marked arterio-sclerosis, degenerative changes in the kidneys, and thrombosis of the coronary artery were found.

Case V.—The urine was light-yellow in color, slightly cloudy, faintly acid, with a specific gravity of 1023. No indican-reaction was obtained. On boiling, after the addition of acetic acid, as well as with nitric acid, no albumin was detected, but with trichloracetic acid a trace was demonstrated. Microscopically, hyaline and slightly granular casts were found. Clinically, the case was one of albuminuria Da Costæ; a few weeks previously albumin was obtained on boiling and with nitric acid to a degree that would have directly excluded the man from life-insurance. The same may be stated of all the cases of albuminuria Da Costæ that I have observed in the course of recovery.

On p. 481 of The Medical News Dr. Stewart says: "With trichloracetic acid, unless the response be frank and outspoken, . . . the nature of the result must remain in doubt and cannot be utilized to account for the symptoms, if nephritis be suspected, as it is, perhaps, more than likely not due to serum-albumin." From this we may in the first place conclude that the response to the trichloracetic-acid test obtained in his eighty-two positive cases was *not frank and outspoken*—and why then call the reagent uncertain and dangerous. If such be the case, and it could not be otherwise, as Dr. Stewart would then have without doubt agreed that all of his 105 cases were albuminurics, it is rather surprising to me that he speaks in such a positive manner of this reagent as being uncertain and dangerous. On further reading, however, the zone of contact is described as varying from a very narrow ring in the least marked to one ot many lines in thickness in the most marked. I must confess that I should always call a ring "many lines in thickness" a frank and outspoken reaction, and in my personal experience at least I am sure that I have never met with such a ring in a *normal* individual.

Now, as far as normal material goes, Dr. Stewart appears to be laboring under the same delusion as Senator and others, namely, that a person must be healthy because he considers himself healthy. In life-insurance work the remarkable health of the applicants is frequently most striking, and only recently have I had in my hands a case of this kind in which all questions as to indigestion, habitual constipation, headaches, etc., were promptly answered in the negative, and a history of unusual health given. In this case albumin was found in large amount, not only demonstrable with the trichloracetic-acid test, but also upon boiling and the addition of nitric acid. The patient later applied to me for treatment, and subsequently furnished the information that his digestion had been miserable for years and years, that he was worn out, felt weak, etc. The cases of Dr. Stewart in which a ring many lines in thickness was observed I should most decidedly regard as cases of true albuminuria, and suggest not only a most careful physical examination, but also an inquiry into digestive derangement, a quantitative estimation of uric acid and oxalic acid in the twenty-four hours' urine, and a careful microscopic examination. To the frequent occurrence of albumin in the urine of young men, particularly associated with an increased elimination of uric acid or oxalic acid, or both, Da Costa has drawn attention in the *American Journal of the Medical Sciences*, 1893, No. 1: a condition that I myself have been able to observe quite frequently.

As far as the "fine ring" is concerned, furthermore, this is merely an optical delusion. Every urine is slightly turbid, and this turbidity will become more marked, and particularly so at the point of contact when brought together with a clear solution, and becoming more marked as the specific gravity of the reagent used approaches that of the urine. With nitric acid this is less marked than in the case of the trichloracetic-acid solution, the specific gravity of the former being greater than that of the latter. In this respect I fully agree with Dr. Stewart when he says that the reaction must be frank and outspoken, but differ

with him in so far that, as I have already stated, I must regard a ring many lines in thickness as a plain and outspoken reaction, such as is not to be found in a normal individual. I should also state that I have applied the trichloracetic-acid test to urine of both normal and pathologic subjects hundreds and hundreds of times with a negative result.

In conclusion, I wish to correct an erroneous statement that Dr. Stewart makes when he says: "Since writing the foregoing I have learned that trichloracetic acid has ceased to be regarded with its former favor in this—the Johns Hopkins—hospital, especially by Professor Kelly, for the reason stated—its impracticable delicacy." The trichloracetic-acid test is used in Dr. Osler's department now, as formerly, whenever in any case the nitric-acid test and that of boiling failed and the case is regarded of sufficient importance to warrant a more careful examination of the urine. In the report of the urinary examination of ninety-one gynecologic cases by Howard A. Kelly, M.D., and Albert A. Ghriskey, M.D. (*Johns Hopkins Hospital Reports*, 1890), the following may be read: "The promptness of the reaction with trichloracetic acid, as well as its delicacy, commends its use." At the present time it is true that the acid is no longer used in Dr. Kelly's department on account of its delicacy, and I freely admit that its delicacy is too great for the surgeon in general, who looks for definite renal changes, *i.e.*, for the existence or non-existence of nephritis. I must, however, emphasize that it is high time that both surgeons and internal clinicians should recognize the fact that the presence of albumin in the urine is not necessarily indicative of nephritis, and is not so in the majority of the cases in which it is found, and that the subject of albuminuria is now undergoing the same process of evolution that we have seen occur in the case of dyspepsia. Our attention and energy should be directed toward a scientific classification of the various forms of albuminuria, and the clinical recognition of the association of albuminuria with definite metabolic disturbances, rather than toward fault-finding with tests as to the practicability and extreme value of which there appears to be no doubt.

Respectfully, CHARLES E. SIMON.

1302 MADISON AV., BALTIMORE, MD.

To the Editor of THE MEDICAL NEWS,

SIR: I beg to thank you for referring to me for brief reply Dr. Simon's rather voluminous protest to the conclusions of my paper on fallacies attending the employment of delicate tests for albumin in the urine. Stripped of quibble and repetition, Dr. Simon's criticism amounts to the following: The material furnishing results was unfortunately chosen; a number of the 105 cases were not "normal" individuals; in those that were and the reaction consisted of a fine ring, the latter was an "optical delusion." Dr. Simon's own experiments with trichloracetic acid have invariably shown that a reaction with this reagent is a reliable proof of a departure from health, indicating disease, renal or otherwise. Incidentally several errors in statement are asserted to occur in my paper.

I distinctly stated in the article criticised, that it was not an inquiry into the frequency of a so-called physiologic or functional albuminuria. It was prepared to form part of a discussion at the meeting of a medical society, and was intended merely as a preliminary introduction to a general study of the subject of albuminuria. It represented a brief inquiry as to the frequency of reaction of urine to certain delicate tests, from a fairly large body of young men who regarded themselves as in ordinary health. The specimens, as stated, were collected for me by Dr. L. Wolff (from his class in urinanalysis in Jefferson College) and are still regarded by him, I am permitted to say, as representing unusually fair material for such experiments. Dr. Wolff, in announcing to the class the object for which the specimens were desired, conscientiously endeavored to fulfil my wish, so far as was possible, to procure the urine of "*normal individuals, those* [in other words] *so far as was known that were without evidence of renal disease.*" Dr. Simon, in disregarding this important limiting clause, as he does whenever he quotes the word *normal*, perverts my very obvious meaning. If he had given a little attention to the literature of the subject of functional *albuminuria major* he would have found that my percentage of gross albuminurics, in nearly all of whom the presence of albumin in the urine was found to be cyclic and probably the result of fatigue, was, though high, not remarkable. He would have found that it is not uncommon to occasionally obtain a marked albumin-reaction to nitric acid (such as would also be "frank and outspoken" with trichloracetic acid) in a subject normal as regards other evidence of nephritis than the presence of albumin.[1] In a second series of thirty-five cases, mentioned in my paper dealing with the reactions of nucleo-albumin, which appeared in THE NEWS, July 14, 1894, p. 29, nearly all of which were furnished by Dr. G. M. Gould from among his acquaintances, the reaction with trichloracetic acid was also positive. These were, as detailed, morning specimens from young adults in apparently robust health. In none of the total 140 was there the slightest cause evident for deception on the part of the donors as to their physical condition, as might be the case in life-insurance or civil (compulsory) examination. I was previously unacquainted with any of those contributing save six. The two with cardiac murmurs, which were discovered as the result of subsequent examination, were, like ourselves, previously unaware of the existence of a heart-lesion. The fact being very apparent, after a large number of these examinations had been made, that probably all normal urines reacted to trichloracetic acid, it was not deemed necessary, in view of the amount of work that would be entailed, without a number of assistants, to make exhaustive physical examination of all those concontributing, or undertake microscopic examinations of the urine other than the specimens reacting to the less delicate tests. Microscopic examination was made in most of the cases of major albuminuria as well as frequent chemical examination of specimens of urine furnished by these on other occasions. The paper, prepared as it was to form a part of a discussion, was written before these details could receive adequate attention. As to the nineteen cases that I stated showed no

[1] My meaning of the words "frank and outspoken" as applied to the extent of the trichloracetic-acid ring, as indicated by the context (THE NEWS, May 5, 1894, p. 481, 2d col., 3d par.), is so evident that it is needless to notice the portions of Dr. Simon's criticism referring to them.

evidence of renal disease, and concerning which Dr. Simon makes an inquiry, he will find that the context of the portion of my paper referring to this point shows that it is to *physical examination* that I refer.

In the application of the tests as detailed I was careful that another beside myself should simultaneously view the results obtained, in order that all question of error should be eliminated. In the series of 105 examinations I had the kind coöperation of Dr. Henry Leffmann, a chemist of whose repute it is unnecessary to speak. In the second series, mentioned in the later paper, in which trichloracetic acid was the only delicate test employed, the results were studied with me by Dr. L. Wolff, who, as is well known, has for years been demonstrator of chemistry and urinology in Jefferson Medical College. So that, in view of the agreement of these gentlemen with me as to the nature of the results as criticised, an attempt on Dr. Simon's part to explain as an "optical delusion" the more delicate reactions obtained, which in his work he is unable to note, save in selected cases, is simply puerile, and not worth discussion. It may, however, be stated that the influence of shading, inclination of tube, and especially the effects of heat, rendered all chance of illusion impossible, even were his curious statement as to the relative specific gravity of nitric acid and trichloracetic acid accurate. This statement, however, is both inaccurate and misleading. The solution of trichloracetic acid as employed by me was a thoroughly saturated one, as Dr. Simon should have seen from reading my paper, for I lay stress on this. This same solution is always presumed to be used in testing for albumin, and it was stated to have been employed by Dr. Reese in his experiments. Now, while the specific gravity of nitric acid is 1.41, that of a saturated solution of trichloracetic acid is considerably greater than this. A solution recently made, and now on my shelves, has a gravity of 1.56. This, from the manner of its preparation, is regarded as of somewhat less density than that employed in the experiments. In my paper especial stress was laid upon variation in result due to carelessness in the preparation of a concentrated solution. It is probably to some such fault in technique as this that Dr. Simon's lack of result is due, and if he is using a dilute solution he may have encountered optical illusions of the nature of which he writes. If, however, an optical "delusion" could be thus produced, it would become evident, if not with nitric acid, at least with picric acid solution, with Millard's test, and other reagents whose specific gravity more nearly than trichloracetic acid approaches that of urine; but this source of error, I am confident, can be excluded. But merely for the sake of argument, granting that those trained in urinalysis might be deceived through an optical error, then this would be the very best argument against the practical utility of the trichloracetic-acid test, for Dr. Simon apparently reserves for himself alone the power which he denies others also trained in chemical manipulation, of distinguishing between an "optical delusion" and an actual, fine ring, significant of a trace of albumin. For, on turning to the report of the five cases in his letter, it is evident that this same fine ring which I have shown may be encountered in the urine of all in health, was present in each. It is stated that in none of the five did a reaction occur with heat or with nitric acid, but that in the first "with trichloracetic acid a fine ring was obtained," and in the others also, a "trace of albumin" was so noted!

As to "our modern standpoint in reference to the significance of tube-casts," that their existence depends upon the presence of albumin, I would refer Dr. Simon to literature more modern than that which he quotes, which assigns a totally different origin for renal cylinders. This view, which I believe is that now generally accepted in preference to the more antiquated and less probable one cited, Dr. Simon will find, with certain references, in the latter part of a paper by myself in The News of April 14, 1894, p. 393. It is there stated why I hold that serum-albumin (or globulin) may be absent and nucleo-albumin present in certain cases in which casts are detected in the urine.

Several of Dr. Simon's statements, however foreign they are to the point at issue as to the utility of trichloracetic acid as a clinical test for albumin, and quibbling as they do with the facts, demand special notice, as, uncorrected, they must inevitably lead to a false impression in the minds of readers not familiar with my work. With a careless disregard for accuracy, in unison with the general tenor of his letter, he states that I have falsely read Dr. Reese's figures. I have but to refer to that portion of my paper in which this so-called false reading appears to show how absolutely incorrect such a statement is. After remarking that many cases had been encountered, the urine of which responded only to trichloracetic acid, I further remark that "in a number of these cases (11) granular, epithelial, and hyaline casts were found." Dr. Reese's report distinctly reads: "In 11 of these cases granular, epithelial, and hyaline casts were found."[1]

Again, the statement that I appear "*to regard the boiling and nitric-acid tests as representing the extreme limit of delicacy for the detection of albumin!*" is totally without warrant. My meaning clearly is, as any one unbiased reading my paper will acknowledge, that these tests represent, from our present knowledge, the limit of *practicable* delicacy; and there is no question that the most conservative of internal clinicians are rapidly coming to this conclusion. Among a large number holding the view that Dr. Simon criticises, I need only mention Tyson, of Philadelphia, and Saundby, of Bristol;[2] and Shattuck,[3] of Harvard, who thinks similarly, in a recent paper on the subject of albuminuria quotes Prof. E. S. Wood, of the same school, as also of this view. This opinion was also strongly maintained in the recent discussion of my paper on "Nucleo-albumin" before the College of Physicians of Philadelphia. Such men as Prof. J. M. Da Costa and Prof. J. P. Crozer Griffith questioned the practical utility of the more delicate tests. Prof. Da Costa remarked: "I am more and more coming to the conclusion that delicate tests for albumin are of little use to the clinician. I believe the saying of Grainger Stewart to be correct, that 'if heat and nitric acid properly applied show no trace of albumin, albumin may for practical purposes be discarded.'" That this view is

[3] Boston Medical and Surgical Journal, June 21, 1894, p. 613.

prevailing among the most enlightened of life-insurance examiners is evident from the fact that at a recent meeting of the Life Assurance Medical Officers' Association, of London, it was held that "urine which did not show a trace of albumin with the boiling and cold nitric-acid tests properly applied might be considered free."[1]

As to the erroneous statement that I am alleged to make concerning the waning favor in which trichloracetic acid is regarded in the Johns Hopkins Hospital, especially by Dr. Kelly, I fancy it is plain enough to any one reading the curiously worded correction of Dr. Simon, that he unconsciously acknowledges the correctness of my assertion. I might here state that as my informant in the matter was Dr. Ghriskey, I had no doubt as to the accuracy of the statement as quoted.

Finally, to conclude, the essence of the whole question is whether or not the trichloracetic-acid test is or is not of practicable clinical delicacy. My own view, further elaborated in the paper on nucleo-albumin (THE NEWS of July 14, 1894), and based on good evidence, is very decided as to its inutility. I show that, with *careful* technique, the indications point to an albumin-reaction being obtained with any specimen of all urines from the healthy. The questions there considered, as to the nature of the albuminous body reacting, whether serum-albumin or nucleo-albumin, is without practical bearing on the point at issue. That an albumin-response may be unquestionably obtained in all urines indistinguishable from that of serum-albumin, my results in a series of now over 150 consecutive cases so strongly show that I am forced to the conclusion that Dr. Simon's negative results in his large number of cases must simply be due to lack of proper technique in the application of the test, or to failure of observation; there is no other explanation tenable, and direct evidence of the former is at hand in his statement as to the density of the solution of trichloracetic acid used by him.

It is, perhaps, unnecessary to state that I shall be glad to practically demonstrate the correctness of my conclusions to any one sufficiently interested who will furnish specimens of urine from those not renal suspects.

Respectfully, D. D. STEWART.

2620 N. FIFTH STREET, PHILADELPHIA.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.[2]

Sixty-second Annual Meeting held at Bristol, July 31, August 1, 2, and 3, 1894.

FIRST DAY—JULY 31ST.

DR. EDWARD LONG FOX, of Bristol, delivered the President's Address, which was entitled "On the Medical Man and the State." After a word of thanks, and after extending a hearty welcome, reference was made to the last meeting of the Association held at Bristol, which was the thirty-first, and had taken place thirty-one years before. Then the work of the meeting had not yet been divided into sections, and no one dreamed of the pecuniary condition of the Association ever being what it is today, or that branches would be planted, as they are, in most of the British Colonies and dependencies.

As a body the medical profession is above party. Its highest aspirations tend to the formation of a pure commonwealth. The poor, the sick, the criminal are its daily study, primarily for the relief of the individual, but with nobler and farther-reaching aims, namely, that poverty may be mitigated by more healthy surroundings; that sickness may be diminished by the education of the nation in the wiser laws of health, by increased temperance, and by knowledge from an early age of the common facts of physiology; and that the criminal class in the future may occupy narrower limits, because no longer the victims of a debased heredity. Poverty, disease, and crime—these are the objects of its investigations as a body, these are the foul blots in the State for which it seeks amelioration.

What numbers of intellectual people, whose work should be so high in poetry, in art, in political or professional life, in commercial undertakings, and even in manual labor, are unfitted for giving their best to the State by an unhealthy environment, by ignorance how to use and how to husband their brain-power, or by yielding to this or that self-indulgence, the very yielding a neurosis! It is but a truism to say that a model State needs the best intellect of each and all her children. Medical men have to work against hereditary influences, induced by the ignorance of many preceding generations—the "good old times," as they are so fondly and so falsely called. But the work is being done. From the highest to the lowest in the State each individual must be brought to recognize that his power of doing good, of duly filling his appointed place in the commonwealth, of carrying out the highest form of altruism, depends in wide measure on his ruling his life in accordance with physiologic laws, for a knowledge of which the world is mainly indebted to members of the medical profession.

All science is cosmopolitan, and medical science, perhaps, especially so. This or that point may have been brought into prominent notice in England, on the Continent, in America, or elsewhere. But the profession in every State is quick to recognize everything that bears upon the subject it has at heart, the well-being of the human race.

Step by step the need of medical guidance is permeating more or less every branch of the public service. *Experientia docet.* What thousands of lives have been saved by the careful observation of the sources of disease by medical men in various parts of the world! by none more ably than by the medical officers of the naval and military services. In their observations upon cholera, yellow fever, and the various forms of malaria, for instance, especially such as in some of their symptoms simulate yellow fever, some of the best work has been done by the medical officers of the army and navy.

The chief need of an ideal State, apart from the legislative and executive departments, is, that the people should be healthy, strong, temperate, and wise. Whatever the form of government, whatever the strife of parties, the nation made up of indi-

viduals is the only ruler. The medical profession has to deal first with individuals, and then with conglomerate bodies of men. Granted a strong development, founded partly at least on obedience to the facts of heredity and on good sanitary laws, the race will and must advance in all physical and mental conditions. So far from being considered, as in Plato's time, as either gainers of money or tenders only of the sick, it is the proud boast of the profession that much of the medical thought of the day, and for many years past, has been devoted to the prevention of disease.

Speaking of Jenner, it was said that he not only created a sure method for the prevention of the most terrible scourge England has ever known, but unwittingly laid the foundation of all microbic pathology. His reward was that each year he saved from death in England alone thousands of lives; and perhaps three times as many owed to him their immunity from the disfigurement and the local diseases consequent on smallpox. It was considered monstrous that in less than one hundred years from the birth of vaccination, the great work of this benefactor to the State should be rendered partially ineffectual by the crazy cry of the liberty of the subject. Should the men be left untouched and unhindered, who, from faddish fears of the evils of vaccination—evils that might be entirely avoided by the use of calf-lymph—are endangering thousands of their fellow-citizens, and doing their utmost to interfere with the only reward to which Jenner looked forward, the well-being of the human race?

It is in the realm of investigation that the medical profession has given some of the best service to the State. Enormous advantages have been conferred upon the State by the light thrown by many investigators on the subject of bacteriology. Already much is known about abscess, enteric fever, diphtheria, cholera, pneumonia, tuberculosis, tetanus, and glanders. Already M. Pasteur's investigations have brought the death-rate from rabies to less than 1 per cent. Already, through the efforts of the same great experimentalist, millions of sheep are being inoculated against anthrax in various parts of the world. Already antiseptic surgery, the splendid result of the work of Sir Joseph Lister, may claim to have made possible hundreds of operations, hitherto too dangerous to attempt, and to have saved thousands of lives. The whole course of medical treatment is being revolutionized by these studies. The coming generation of doctors will have their time taken up, even more largely than in past years, in rendering persons immune to the attacks of disease. It is known now that abscesses caused by staphylococci have a tendency to remain localized, whilst those from streptococci are often followed by metastatic abscesses, as in erysipelas, puerperal fever, and ulcerative endocarditis.

It is now known that the tubercle-bacillus is found in chronic bone-disease, and that if present alone the disease is a chronic one, whilst if the streptococcus pyogenes is present also the disease is more quickly fatal; that the suppurations accompanying tuberculosis are due, partly to the tubercle-bacillus itself, or, rather to the poisons resulting from the action of that bacillus, but partly also to other microörganisms; that the bacillus diphtheriæ is found chiefly on the surface of the false membrane, and that the fatality of the disease depends on the poison secreted by the bacillus, whilst the presence of streptococci renders the disease more grave, the increased virulence being due to the presence of both these organisms together. Acute pneumonia is caused by the pneumococcus of Talamon-Fraenkel, although often in association with the streptococcus pyogenes. This pneumococcus, too, may produce abscesses in patients free from pneumonia, as in purulent pleurisy, ulcerative endocarditis, and suppuration of the nasal fossæ. The fact that this microbe is present in the saliva of healthy people proves that these diseases have also a non-microbic element. Some condition of the sympathetic influencing the caliber of the bloodvessels or some morbid condition of the vagus or of the accelerator nerves, or some inherited vulnerability, with all its possibilities, must probably be a precedent factor. The typhoid-bacillus is often accompanied by other microörganisms, especially the streptococcus pyogenes or the staphylococcus aureus and albus. The study, too, of tetanus might, if time permitted, open up a further story of the mode of destruction of these microörganisms, as the leukocytes refuse to take into their interior the tetanic bacillus when other microörganisms are present in the wound at the same time.

Is it not remarkable that in a practical country like Great Britain the existence of such beneficial institutions as Research Laboratories is left to the liberality of private individuals? Is it not remarkable that the State has nothing to do with them, except by utilizing the advances in preventive medicine, engendered by the labors of those that are connected with them.

Perhaps next in importance to the study of bacteriology is the good work done by medical men, and in part acted on by Parliament, on the subject of noxious trades. Here especially does the State owe much to members of the medical profession.

There is now no portion of the human frame in which disease is not being traced to its source by medical philosophers with a view to its prevention or its cure. In no department has better work been done than in the investigations of the nervous system. In no department has the result of such investigations been of more permanent utility to the well-being of the State.

What is still partially needed for the brain itself has been in large measure accomplished for the medulla oblongata. How many lives have been preserved to the State by the more accurate knowledge of this small portion of the nervous system. Forming a connection between the brain and spinal cord, in some respects belonging to the spinal, in others to the cerebral system, how many centers are represented here.

Sympathetic reference was made to the late Prof. Charcot.

Good work has been done in the medical investigations of akromegaly and myxedema. The peculiar

symptoms classed under the latter denomination are strikingly improved by the injection of the organic liquid extract from the thyroid gland. This is only one instance of the benefit conferred by the use of these organic liquid extracts from the glands and other organs. The use of cerebrin in neurasthenia, tabes, and even in some cases of epilepsy, of thymus fluid in pseudo-hypertrophic paralysis, of a liquid extracted from the medulla of the bones in the treatment of anemia, debility, and lymphadenoma, opens up a new line of thought both in physiology and therapeutics. The value and importance of such investigations is still *sub judice;* but when, as in myxedema, some morbid condition of the system depends upon the absence or disease of a certain organ, it was not unreasonable to hope that the exhibition of this organ, or of healthy preparations from it, might be beneficial. And this mode of experimental therapeutics will lead to a better classification of disease and to the power of generalization of many morbid phenomena that hitherto have been absolutely unrelated.

This new mode of treating myxedema leads up also to the question of feeble-mindedness in children, cretinism, and especially sporadic cretinism, which is only myxedema in childhood.

The subject touches biologists on questions of heredity, surgeons with reference to the relief of synostosis, and physicians, legislators, and criminal lawyers in its various phases. It is being learned that, except in the case of the microcephalous, cranial developments do not help much in these researches—not even pathologic appearances. The power of attention, and the consequent results of education, are almost the only trustworthy data for differentiation. But this benefit to the State, due mainly to members of the medical profession, obtains not only in raising some of these afflicted ones to a dim apprehension of the abstract, but many more to a condition in which they are partially, at least, able to earn their own living, and be no longer wholly a burden to the community.

It is a mere truism, more or less generally recognized, that for hard work, for self-abnegation, for devotion to the good of others, the medical profession, from student-life onward, is a type for the imitation of the nation at large. Plato spoke of medical men with some disdain as "gainers of money," but that sneer can never be applied to the medical Poor-law officers. Amid the constant pressure of hard work, amid difficulties of all sorts and kinds, with continual disturbance of rest, and with demands on their mental resources more incessant than is usually experienced among the rich, the Poor-law medical officer, either at the workhouse or in district-work, knows no repose, and with a salary so inadequate that the State ought never to sanction it, becomes the hearty and untiring friend of the poor, a pillar of the State not only by the results of his devotion to his duties, but by the splendid example of his life.

But professional influence permeates the nation in many directions. It is the enemy of excess of all kinds. The medical experience of the day has set itself against excess. And not only as to food. A vast number of the profession may not be total abstainers from alcohol, but the majority are examples and teachers of temperance.

They were medical men who made experimental observations that placed this question on a basis of truth and common sense. How important is it for the nation to know that alcohol is, with certain exceptions, unfitted for childhood: that any excess in muscular work, as in the forced march of an army, is rendered far more difficult by its use; that it not only fails in giving power in the work of the muscles and the heart, but acts distinctly as a depressant; that it never enhances the temperature of the body, and that in its pure state it is in no sense food.

It is to medical influence that the sensible care of children, the due relation of muscular and of mental work in schools, the methods for regulating the health of body and mind amid the railway pace of modern life, the prolongation of existence to a ripe old age, are almost wholly due. What assistance, too, does it give so often to the law, though doubtless in this relation it would be better that in controversial cases the medical witnesses on each side should meet in consultation.

Second Day—August 1st.

The Address in Medicine was delivered by Sir T. Grainger Stewart, of Edinburgh. He took up for consideration the nature and treatment of influenza.

He cited evidence of an epidemic occurring on the Continent of Europe in 1387 and of another in Scotland in 1562. Particular reference was made to the complications and sequelæ of the disease.

The alimentary system was affected in a great variety of ways. Apart from the disturbance attending the acute attack or primary disease many patients suffered for weeks or months afterward from various digestive troubles. In such cases there was no doubt that the gastric symptoms were due to influenza, but it was not easy to say whether the gastric mucous membrane was the structure primarily affected, or whether the nerves supplying the stomach were at fault.

The hemopoietic system exhibited innumerable changes. Ordinary anemia was commonly observed, and forms so severe as to warrant their being called pernicious now and then occurred. But among the most important of the blood-changes noticed was purpura hæmorrhagica.

It is difficult to say how these blood-changes are brought about, but it must be kept in view that at least one of the structures standing in important relation to the blood is affected, namely, the spleen; that it is often enlarged in influenza as it is in so many fevers; and it is not unreasonable to suppose that the bone-marrow and other structures may be similarly involved, and that the blood-changes may be due to these.

But, apart from structural alterations of the blood, chemic changes have been frequently observed to result from influenza. Perhaps the most typical is the occurrence of gout during convalescence from an attack.

Diabetes mellitus has been found to stand related to the influenzal process in two ways—for those who have been suffering from diabetes and have taken influenza showed a proclivity to diabetic coma, and, in a considerable number of cases, the diabetic process itself took origin just after influenza.

It is possible that changes in the central nervous system may afford the explanation of the occurrence of diabetes in the sequence of influenza, or it may be that organs such as the liver or the pancreas, which stand related to the transformation of sugar in the economy, may be directly affected by the morbid process.

The circulatory system exhibited some of the most interesting post-influenzal phenomena and of considerable variety. In some instances the heart's action was unduly slow, in others excessively rapid; in the first instance as a result of a diminution of the action of the cardiac motor nerves; in the second of a diminution of inhibition. In some cases the heart was rapid and irregular, and there existed marked dropsy as a result of increased backward pressure from the failure of the heart's action. In some of these cases it is probable that degenerative changes occurred in the muscular fiber of the organ. In other cases a fatal result occurred from sudden failure of the heart's action, sometimes with, and sometimes without, fatty degeneration of the muscular fiber. Pericarditis was frequent, endocarditis occasional, and perhaps myocarditis also.

The respiratory system suffered changes more frequently in connection with influenza than did any other organs of the body. In some cases bronchitis persisted for a longer or shorter time. In some of these, without doubt, that inflammation was of a specific influenzal character, the bacilli being demonstrable in the sputum all the time. In others it was, perhaps, of a simple non-specific kind. The influenzal process has been observed in relation with bronchitic asthma. The explanation is to be found partly in the local effects of the influenzal process, and partly in the disturbance of the nerves supplying the bronchial tubes, which stand so definitely related to asthma.

Pneumonia was by far the most formidable sequel of influenza, and displayed marked differences of type from the normal course of the disease. Moreover, its fatality appeared to vary in the recent epidemics. Every variety of pneumonia presented itself, but the catarrhal was most frequent, and that of an acute and peculiar type.

The croupous form was also frequent, and pleurisy and empyema accompanied it in a considerable number of instances. In explanation of these complications it may be assumed that the catarrhal pneumonias were due to extension of inflammation from the bronchi to the ultimate air-cells. In the cases of croupous pneumonia the organisms of Friedländer and Fraenkel were abundant enough, and streptococci were found in the empyema cases. There was no reason to suppose that these organisms were more abundant or more active during the influenza epidemic. The difference lay in the greater susceptibility to the action of the organisms induced by the influenzal process.

The relationships between influenza and pulmonary tuberculosis were equally striking and varied. In not a few instances pulmonary tuberculosis originated in an attack of influenza, and frequently tuberculous patients, whose condition had been quiescent or scarcely advancing, suddenly developed pronounced symptoms, and went on rapidly to a fatal result. The relationship between the two processes seems to depend on the fact that influenza so affects the system as to render it more susceptible to the action of the tubercle-bacillus.

Among the morbid conditions of the integumentary system which attended upon the process may be mentioned the critical efflorescence so often observed at the height of the disease, and the desquamation which speedily followed on that inflammatory action. There was also a tendency to chilliness of the skin, and to copious and exhausting sweating, which often persisted for months after the acute symptoms had passed away.

The urinary system was affected in many ways; sometimes there was a mere passing albuminuria, sometimes a formidable hematuria or serious inflammation of the kidneys, and in some epidemics, as in one of those recently described in Egypt, such changes were frequent, and in a considerable number of instances proved fatal by uremia. Some patients exhibited a susceptibility to vesical inflammation. The reproductive system also showed manifest changes in both sexes—the functions became greatly impaired.

But the nervous system suffered most frequently. In every case of influenza during the acute stage disturbance of that system was pronounced, and nervous sequelæ were extremely common, serious, and persistent.

Eye-changes were numerous, inflammation and ulceration of the cornea, conjunctivitis, iritis, glaucoma, asthenopia, optic neuritis, optic atrophy, paralysis of accommodation, dyschromatopsia, blepharospasm, and many more. Diseases of the ears were common, especially otitis. Changes in the sense of smell and taste were observed; sometimes in the way of diminution, sometimes in the way of perversion, and sometimes in the way of exaggeration of function.

The locomotory system also sometimes showed important changes in respect of bones, joints, and muscles.

This list of complications includes morbid processes which arise in a great variety of ways. An etiologic classification of morbid processes may perhaps serve to render this more distinct.

1. *Diseases which owe their Origin to the Invasion of Foreign Organisms, particularly Microörganisms.* Among the maladies which follow influenza there are undoubtedly several belonging to this group, as, for example, tuberculosis and pneumonia.

2. *Diseases due to Faulty Chemic Action within the Body* either in respect of (1) the introduction of toxic substances from without; (2) faulty gastro-intestinal digestion; (3) faulty chemic transformation of the blood and other elements of the body; or, (4) faulty elimination of waste products. This group is well represented among the after-maladies

of influenza, the gastro-intestinal cases affording illustrations of faulty digestion: the anemias, purpura, diabetes, and many cases of gout affording examples of faulty metabolism, while in some instances gout and other maladies may be induced by faulty elimination.

3. *Diseases dependent upon Faulty Mechanical Conditions.* Illustrations of this group may be found in the swellings of the limbs and other changes following upon thrombosis of veins, and in the dropsies and other results of backward pressure following upon dilatation of the heart.

4. *Diseases dependent upon Faulty Innervation.* Of this group there are abundant examples, as in some of the cardiac and gastro-intestinal disorders, in the feverish attacks, and the profuse perspirations.

5. *Diseases dependent upon Morbid Nutrition of the Tissues, either in the way of Inflammation, New-formation, or Degeneration.* Influenza has shown numerous illustrations of the inflammations, as, for example, in the cases of meningitis, pericarditis, pleurisy, neuritis, dermatitis, while the degenerations are illustrated by the fatty changes in the cardiac muscle.

While knowledge of the clinical features of influenza was increased, still greater advances have been made in regard to the essential nature of the influenzal process. The essential cause of this process has been found to be a bacillus presenting distinctive characters in respect of appearance, staining and cultures, and present in the sputum in enormous quantities.

Even to the naked eye influenza-sputum is characteristic enough. It is of a yellow-greenish color, viscid and tough, generally brought up in lumps or balls, and presenting a nummular appearance in the dish. It varies in quantity from a very small amount up to several c.c. in twenty-four hours. In almost every case it is derived from the nose and pharynx, but in those of any severity largely from the bronchial tubes, down to their utmost ramifications, and from the air-cells of the lungs.

The bacilli are, as a rule, present in enormous numbers in the mucus of the respiratory tract. They are to be found also in the mucous membrane, and to some extent in the neighboring tissues. They are met with in the inflamed patches of the lung, along with the ordinary microörganisms of pneumonic processes. They are occasionally found, but in comparatively small numbers, in the blood, and when there they appear to be dead or dying, being no longer capable of cultivation. They may block bloodvessels in patches of inflamed lung, and they have occasionally been found in different parts of the body, as, for example, in the kidney and the liver.

It seems probable that the constitutional symptoms of influenza result indirectly rather than directly, and for several reasons: 1. The bacteria are not found living, active, numerous in the blood and throughout the tissues of the body generally, and therefore cannot be supposed to be operating so widely. 2. The character of the symptoms corresponds to that of those due to such poisoning.

This conclusion as to the general symptoms which occur in all cases of influenza, still more forcibly applies to the complications and the sequelæ.

In the complications and sequelæ due to the action of other microörganisms than the influenza-bacillus, the influenzal process affords a nidus in which germs may readily multiply; it lowers the general power of resistance to microörganisms; in some cases there probably occurs mixed infection; the bacillus of influenza or its products conferring increased activity upon certain other microörganisms with which it happens to be associated.

The morbid processes complicating or following influenza, and in which faulty chemic action is evolved is explained by (1) the general debility; (2) the special depression of the nervous system; (3) the interference with the processes of gastro-intestinal digestion; (4) interference with the chemic changes in the liver, in the blood, perhaps the spleen, and other organs, which interfere with metabolism; (5) defective action of emunctories, whereby waste-products, failing to be removed by the natural channels of elimination, accumulate within the system, and exert a toxic influence; (6) perhaps the chemic products of the influenza-bacillus itself may interfere directly with chemic transformations.

The morbid conditions due to faulty innervation —the cardiac, the gastric, and the bronchial and the intestinal disturbances—are in most cases due to poisoning, without recognizable organic change, but sometimes as a result of definite structural alteration.

The series of inflammatory and degenerative processes, the inflammations of mucous surfaces, of serous membranes, and of solid organs; those of nerves, of nerve-centers, of the membranes of the brain and cord, and the fatty degeneration of the heart, are probably due not to the bacillus but to its products.

By analogy with studies already made upon anthrax and diphtheria the conclusions may be formulated: (1) That the influenza-bacillus, which is not widely disseminated throughout the body, produces its effects by its chemic products. (2) That these chemic products may probably be of the nature of albumoses associated with an organic acid or acids, or with an alkaloid or alkaloids, which may perhaps be produced indirectly by means of a ferment secreted by the bacillus. (3) It is probable that the production of these substances takes place to some extent in the spleen, which is so often found enlarged in cases of influenza. (4) That these poisonous products act upon nervous and other tissues, producing the great variety of functional and structural changes which are met with in the later stages of the influenzal process.

In the way of prophylaxis, many facts have been ascertained which are fitted to suggest and even justify the adoption of preventive measures, although it must be admitted that the application of these measures is by no means easy.

While recent facts have thrown doubt upon the old belief in the atmospheric spread of the disease, evidence of an overwhelming force has accumulated in favor of its spread by contagion.

Epidemics do not always spread with the prevailing winds; they are independent of season and weather, are never known to travel faster than men can travel, never occur among persons so placed as to preclude communication by human agency; as a rule, appear first in each country in the ports of entry or in the frontier-towns, and in the busy capitals which were most active in intercourse with neighboring lands which had become affected; as a rule, country places remain longer free than the busy towns, even although they might be nearer the countries already invaded by the disease; the individual members of the communities who were most in contact with others were first affected; from them it spread to others with whom they were associated; among persons that were wont to congregate in crowded, and especially in ill-ventilated buildings, and where people were closely associated in public institutions, the disease came more speedily to its height and was sooner got over than when men were more secluded from one another.

Another important fact which has been made out is the shortness of the period of incubation. Sometimes the symptoms appeared almost immediately after exposure. A consideration of the brevity of the period of incubation makes clear the rapidity of the epidemic spread.

As the great majority of people are susceptible to the action of the influenzal poison, and as one attack confers no immunity to another, and as the disease often spreads from cases which are not severe and appear trifling and unimportant, its return in a community, even by contagion, ultimately surpasses what anyone could expect.

But the spread is not exclusively by direct intercourse between the sick and the sound; it is often by means of fomites. Post office and railway officials were specially apt to suffer early, and from them as centers the disease sometimes spread through the community, and these facts afford instances of the tendency the disease had to spread by letters and by parcels.

Outside the body of the healthy person the influenza-bacilli might be prevented from producing its effects, if those who have become affected with the disease could be effectively isolated. Every sneeze, and every cough probably, scatters the germs throughout the atmosphere, and if those who are affected could only be isolated the danger would greatly diminish; but isolation in a general way is impossible, and that because many cases of true influenza are so mild as to escape detection, and because even when the case is severe, infection is often spread before diagnosis is possible. But, on the other hand, now that people have ceased to regard influenza as a trifling and unimportant malady, and have come to know that it is certainly contagious, precautions have often been taken that were scarcely dreamed of in former epidemics. Infected individuals have isolated themselves, and thereby have saved their neighbors from contamination. People suffering from disease of the heart or lungs have been kept scrupulously away from the infected, and have thereby escaped what would have been to them a terrible danger. Schools have been closed, with the result of diminishing the severity of certain outbreaks, and no doubt when the next epidemic of influenza occurs, precautions of this kind will much more generally be adopted.

But even when isolation is impossible much good may be done by destruction of the sputum and of the nasal secretion. If patients expectorate into vessels containing sufficient disinfecting fluid, or into pieces of linen which are immediately thrown into the fire, innumerable quantities of noxious germs may be destroyed in each case. So, precautions as to the discharges, if once efficiently taken, would tell materially upon the epidemics.

If the bacilli discharged from the body can be thus dealt with, the question arises whether they cannot be dealt with within the bronchial tubes. If this were possible their multiplication and the development of their toxins might be prevented, and the noxious power of the sputum greatly diminished. Inhalations of many antiseptics have been recommended for this purpose; eucalyptus and menthol have been, perhaps, among the most popular. The injections into the trachea of such substances as have proved serviceable in other diseases of the respiratory tract might be tried, such as a 10 per cent. solution of menthol in olive-oil, with or without 2 per cent. of guaiacol superadded.

It is possible that during epidemics of influenza such intra-tracheal injections might confer a degree of immunity upon those exposed to the contagion.

Another question which emerges is whether any means may be discovered of conferring immunity by rendering individuals insusceptible to the action of the germs. Now the mere fact that one attack of the disease confers no immunity to subsequent attacks makes one less sanguine as to the probability of such a material being discovered, but it may, perhaps, one day be possible to supply a preventive treatment by the use of the derivatives of the specific bacillus.

Again, it would be of great service if substances were discovered by means of which the poisonous products of the bacilli would be destroyed or neutralized, and so prevent the secondary results. It is also conceivable that substances may be discovered which would act as physiologic antagonists to the influenza-toxins; but this also is in the meantime mere matter of conjecture.

The last question to be raised is whether the system generally or the organs specially affected can be so acted upon as to combat the injurious effects. There is one lesson which most people have learned from the recent epidemics, namely, that those who are taken with the disease, even in a mild form, ought not to struggle against it and go on with their work, but should yield to the malady for the time, in the hope of escaping or lessening its after-effects. When the after-effects manifest themselves, rest from bodily and mental effort is essential, and careful attention to diet, to protection from cold, to the moderate and wise use of stimulants by those who are accustomed to employ them, and of such tonics as nux vomica, quinin, arsenic, and iron, with special cardiac or other tonics when they are indicated, prove eminently beneficial.

Third Day—August 2d.

The Address in Surgery was delivered by Mr. J. Greig Smith, of Bristol, taking for his subject "The Art of the Surgeon." He pointed out that not only has the surgeon knowledge to acquire but also an art to learn. The art may be of little importance as compared with the science of surgery; there can be no dispute that it is; still, as the servant, the interpreter, occasionally even the improver of the science, it has its importance, and may be worth thinking about and worth discussing.

What is a Surgeon?

The surgeon is, first and foremost, a physician, a man trained in the laws of health and disease, in the ways of preserving health and of curing disease. In person or by proxy he must lean finally on medicine. To his medical training is superadded a special and peculiar education in the treatment of certain diseases which lend themselves to cure by the help of handicraft. The surgeon is a man who can carry the treatment of a class—a small class—of diseases farther than the physician, and that is all. The physician, on his side, goes beyond the surgeon. But both meet. In old times the surgeon was practically the slave of the physician; later on he struggled up to the dignity of being his enemy. To-day he is his equal and his helper. They join hands over the same patient, each seeking from the other some special help in healing. And herein to-day is the difficulty both of the surgeon and of the physician. Each is driven to his wits' end to meet the manifold demands made on him by the other. This is their only rivalry, a goodly and a wholesome one, leading to new victories over disease.

Amongst other arts and crafts the surgical stands alone in extraordinary breadth of its foundation on science. The painter is not expected to know the sciences of chemistry, botany, geometry, and optics, which intimately relate to his art; nor is the sculptor supposed to be familiar with geology because he works in clay and marble. Possibly both painter and sculptor would be the better for a scientific knowledge of their materials; but such knowledge is subsidiary and unessential. To the surgeon wide scientific knowledge is of prime importance; it is, indeed, essential. His range is almost coterminous with abstract science—something of all of the sciences, a good deal of a few, and everything of two or three, he must know.

Those who arrange the medical curriculum go on adding to it; where is this importation of new subjects going to stop? They go on broadening the base, and adding to the foundation; might not now some thought be given to the raising of the building?

The rolling years add to the pile of knowledge, and the burden becomes heavier to bear. To some the burden is already too heavy; others carry it easily, and even voluntarily add new weight. How to deal with the pile so that it may best minister to good is a problem always seeking solution.

Some would solve it by deliberately casting off part of the burden as being cumbersome and useless. These men say of anatomy that there is too much of it. If surgeons, they say they cut where they have to cut, and if they divide a vessel they tie it. The right kidney they find in the right loin, and the left kidney in the left loin, and they cut down till they come on it. If facts must be borne in mind till examination, there are mnemonic rhymes and cabalistic formulæ to save the labor of the brain. There is, they say, too much anatomy. They say of physiology that it is unstable and uncertain, that it is burdened with an affectation of science called by its young votaries "research;" and they affirm that the young physiologist when he becomes a physician administers a dose of castor-oil to his patient on very much the same principles as his grandmother followed when she gave a dose of the same drug to his father. Pathology also they despise. They call this the science of the "too late;" it helps us when the power of helping the patient is past. From the disintegrated remnants of the deadhouse they say one can no more work back to the beginnings of disease than from the shattered fragments of a fortification the artilleryman can work back to the powder and shot and ordnance which created the havoc.

These men are not few, and they are as honest as their opponents. Mr. Smith, with firm belief, proclaimed the very opposite. If asked of surgery "Are we to lower it so that brains may not be strained; or are we to strain our brains that surgery be raised?" he would answer unhesitatingly, "Let surgery rise if brains fall." Let the weak, or the lazy, or the impatient fall out, but do not let us lower our standard because some men cry that it is too high. It cannot be too high; it can never be high enough. The claims of surgery are such that no test of excellence can be too high for those who seek to qualify themselves for its practice.

Mr. Smith would not favor casting anything away; but he would select, rearrange, and raise. He would gladly see zoölogy, and chemistry, and botany turned out of the curriculum, and placed among the preliminary studies and made part of the preliminary examination. He should like to fill their places in the curriculum with more anatomy and more physiology and more pathology. He would extend and raise education in these branches simply and solely because he firmly believed that the fullest knowledge of them goes to provide the best practice of surgical art.

In the persistent and overwhelming claims of its science, there is real danger that surgery may lose something of its art. The art of the surgeon may, for purposes of comparison, be viewed from two aspects. One is allied to the art of workers in wood and iron, and may be called mechanical. The other aspect has little of the mechanical about it, and is closely allied to a fine art. The mechanical side, the art of the application of tools, is an important but comparatively simple one. Easily learned as it is, it is still worthy of being taught. It is not, perhaps, a good thing that a surgeon should for the first time handle a saw or a chisel, or a drill, or a trephine on a living human bone; and it would be well if surgeons who have much to do with apparatus knew the qualities of the metals and other materials they

employ, and the ways of jointing, and welding, and moulding them to meet the ends desired. It would, in fact, be good for most surgeons to spend a month or two in a mechanic's shop under the severe discipline of a skilled workman. In respect of technical skill in their handling, the surgeon's tools may be placed on the level of the sculptor's spatula or chisel, or only a little higher. The chisel of the sculptor and the knife of the surgeon are mere incidents or accessories in the work to be compassed by the brain-compelled hands. Still, as accessories they have their importance; the surgeon ought to be familiar with his tools. But the surgeon is more than a mechanic; he has work to do which brings him to the level of the true artist.

The other side of surgical craft may be compared with that which produces what are known as works of art; and this side is by far the most important. Here the work of the fingers is of small moment as compared with the work of the brain. The brain is supreme, and yet in delicacy, deftness, and general preciseness of obedience to the brain's behests, the fingers and hands have great calls made on them. In painting, sculpture, or music, mere manual dexterity rarely is deficient to him who has the artistic soul; or, if there is deficiency, practice and education will do much to remove it. So in surgery, the hands rarely fail to rise to the demand the brain makes upon them if they are trained.

The highest part of the surgical art is more than handicraft; it is braincraft uttered through the fingers. It is not mere manual dexterity or cunning. In fact, mere manual cunning, being a result of routine practice which begets reflex movements, is detrimental to surgical art, which demands the widest possible scope and variety of action. The surgeon's art demands breadth and variety in manual training; the hands must have all-round capacity. By many devices and practisings he may and ought to improve their capacity; but their final and most perfect training is in the actual work.

The skill of the hand depends greatly on the sense of touch and on what has been called the muscular sense. The highest cultivation of the sense is essential to the surgeon.

The sense of touch is trained through the intellect as much as through the fingers; it is helped by comparative appeals to the other senses, and especially to sight.

There are no limits to the demands made on the surgeon's tactile powers. Touch is to the surgeon what hearing is to the physician in diagnosis, and more in treatment. In diagnosis touch tells what sight cannot; in operating in the dark depths of the body it goes where sight cannot, and sometimes it guides more truly than sight could. But always it is the intellect that interprets.

Amongst the plastic arts sculpture, perhaps, presents most points for comparison with the surgical. Each deals with the human body. The sculptor has to know the body externally in architecture, in bulk, and in outline; the surgeon has to know it in the same ways, internally as well as externally, and in sections vertical, transverse, and oblique as well. Each art demands from its votaries absolute fidelity to form; the ignorance that misplaces a tendon in a statue will lead to grief on an artery in an operation. There are similarities in their ways of working, too. The inferior sculptor, by adding here and subtracting there, by measuring and squeezing and scraping, may, after long working, make a tolerable likeness, but never a work of the highest art. The true artist goes straight to the stopping-point and then stops. What this stopping-point shall be cannot be defined, but it gives that sense of true balance between detail and mass which signifies artistic proportion. So in surgery; the surgeon-artist forms a clear conception of the work he has to do and makes straight for the ending of it. Between detail and bulk he determinedly keeps a true artistic proportion. His time is limited, and into this time he must put his best work. He wastes no time over trifles; he is very deliberate over difficulties. The most elaborate finish in both arts is visible when the technical difficulties are greatest. The clean straight strokes of a true artist are visible equally in the work of the surgeon and the sculptor.

The surgeon who is not an artist is devoid of a sense of true proportion. Where one bold cut is wanted, he will make a dainty nibbling dissection. He verifies his anatomy on the way to his work by the help of the director. He goes a little in this direction and retraces his steps; then a little in that direction and returns. He has hobbies, and he rides one or two well. One man turns the peritoneum in, the other turns it out, a third is careful to ignore it. Perhaps he gives one suture to peritoneum, one to muscle, one to fascia, and one to skin, and each suture is perhaps of a different color or a different material, so that Nature may have no chance of making a mistake. His work is not toward one finished work of art, but to the making of half a dozen clever separate studies. Like the sculptor who is good at hair, and works out every one, or the painter who is good at eyes and puts in the dots in the iris, each sacrificing the whole to the part, the inartistic surgeon lingers over his fancies, and so fails to produce finished and harmonious work. His details are not all equally balanced; some are exquisite, some are mediocre, others are bad. The whole work, the whole operation, will not be the best possible for the saving of life; it is not all round a finished work of art. Therefore it is to be condemned.

The surgeon's art has in it not only the elements of boldness, honesty, and simplicity pertaining to the sculptor's art; it leads him in some of its departments into methods of working which may fairly compare with the most delicate amongst artistic pursuits. The finest work of the surgeon makes demands on the delicacy of the fingers little, if anything, less exacting than the demands made on the fingers of the etcher or the line-engraver. The surgeon, as a painter, has to make pictures not only in life size, but in miniature; as a sculptor he has to do not only the full figure and the medallion; his work may also be compared to that of the graver of gems.

The operative art of surgery is truly a high art;

the demands it makes on the hand, the eye, and the brain of the artist are the same for surgery and the fine arts. Surgery and fine art may indeed well be practised by the same man.

Now, of this art of surgery, where and what is the teaching? Where and who are the masters who guide and correct the young artists in their work? It may be said at once, of masters there are plenty, but they do not teach. There is no real teaching of the art of surgery in Great Britain. Here and there a favored few, house-surgeons and their assistants, are permitted to pick up what knowledge they can by looking on and by helping, but of personal guidance in the actual work on the living subject analogous to the guidance given in other arts, surgeons in theirs know nothing. They have to teach themselves by experience alone. Think what this would mean in art-training. It would mean that to paint a thousand portraits is the only way to become a first-rate portrait-painter; to model a thousand figures is to become a perfect sculptor. It means in medicine that the midwife of 5000 experiences is more to be trusted than the obstetric gold-medalist of London University, who can boast of only fifty. And note this further, the young sculptor may with impunity make and break figures to his heart's content; the young surgeon, in learning his art, is not supposed to damage or destroy human beings.

Artists, mechanics, craftsmen of all sorts, learn their work in the workshops or studios with a master to correct their faults and guide their efforts. Surgeons alone have, unassisted, to grope their way to excellence in their art. In his science the student has guidance enough in all conscience, and in his notetaking and his dressing he is sharply looked after. But he is severely left to his own devices to pick up the technics of his craft.

Is this right? That the art of surgery is teachable there can be no dispute, that it is worth teaching is still less disputable. Why, then, is it not taught?

The art can be taught in only one way, the way of teaching all the plastic arts. The young artist must while beginning the practice of his art have a master at his elbow, a master who will criticise his methods and correct them, who will guide him in the use of his hand, his eye, and his instruments, who will in the fullest sense make him his pupil and personally lead him on, step by step, toward such excellence in the art as he himself has acquired.

As a step between anatomy and surgery, the performance of operations on the dead body is of supreme value; it is indeed indispensable. It is the first step toward operative surgery, but it is not operating. For instruction in the living art of surgery, attendance in the operating-theater is of little value. The student sees little, and that little with uninstructed eyes. The student of surgery is just as likely to learn his art simply by attendance in the operating-theater as is the student of the violin to become a true artist simply by going to concerts. In both cases to learn the art the student must work at it; to attain to the highest degree of excellence he must work under a master.

If then the art of surgery is to be perfectly taught, it must be taught to the young surgeon actually operating. And here is the first difficulty. We cannot teach the art to unqualified men; students are not permitted to operate. The teaching must be begun after the student is qualified. As things are at present this is not easy. The pupil of yesterday is a colleague of to-day; when qualified he is supposed to be the equal of his teachers, and therefore above their criticism. It is difficult to imagine a skilled senior in the operating-theater calling attention to the faulty methods of his young colleague; it is impossible to conceive the former pushing the latter aside and showing him how to do it. And yet, if the living art is to be taught at all, this personal way is the only way. Why should the young surgeon more than any other artist fear tuition in the operating-theater? Possibly the presence of young students, of whom he is probably a teacher, would be a chief objection. Then, if the humility of him who truly seeks after knowledge is not forthcoming, must the young students be excluded from operations at which open instruction is given to young surgeons. And it resolves itself into this, that the master has a few qualified pupils, and is present at the operations of these few. He guides them in their work; he points out faulty methods; he advises, and, perhaps, assists; and this he does in the presence of all his pupils.

As a matter of fact, it is doubtful if the young surgeon would fear tuition in public, if such tuition were given honestly and courteously by a man whom he could look up to as a master. There is no method of education in handiwork that can surpass fair criticism of the work before compeers. The mere pointing out of faults calls attention to details which the average onlooker would fail to see. But criticism is not all fault-finding; it calls attention to excellences as well as defects. The pointing out and correcting of faults, and the praising and holding up for imitation of any special excellence in operating might well, to the advantage of all and the discomfort of a very few, form part of the routine education of the hospital operating-theater.

NEWS ITEMS.

The Vermont State Medical Society will hold its eighty-first annual meeting at Montpelier, October 11 and 12, 1894. An interesting program is in course of preparation.

"*The Nursing World*" is the name of a new "monthly journal devoted to the theory and practice of modern nursing," published at Providence, R. I., and edited by Dr. J. E. Brown.

The Cholera.—Thirteen cases of cholera, with six deaths, were reported in Maastricht in Holland, up to July 3d.

"*Health*" is the name of a new publication, which announces itself as a journal of practical hygiene.

Dr. Rudolph Matas has been elected President of the Louisiana State Medical Society.

ATONY OF THE INTESTINE.[1]

BY JULIUS FRIEDENWALD, A.B., M.D.,
OF BALTIMORE;
CLINICAL PROFESSOR OF DISEASES OF THE STOMACH IN THE COLLEGE OF PHYSICIANS AND SURGEONS; ATTENDING PHYSICIAN, MEDICAL DEPARTMENT, CITY HOSPITAL DISPENSARY; VISITING PHYSICIAN, BAY VIEW HOSPITAL.

IN an article on "Atony of the Stomach,"[2] published recently in THE MEDICAL NEWS, I pointed out the great confusion still existing concerning this condition. The same is true to a still greater degree in regard to atony of the large intestine.

Atony of the intestine is usually placed under the general heading of constipation, and scarcely any attempt is made to distinguish the various disorders of which this is merely a symptom. Thus Leichtenstern,[3] in Von Ziemssen's *Cyclopedia*, treats of intestinal atony under the general head of habitual constipation, and does not suggest any method by which this form of constipation may be differentiated.

Henoch[4] considers atony of the intestine one of the most frequent causes of constipation. He devotes considerable space to the treatment of the disorder.

Leube[5] places atony of the intestine among the nervous intestinal disorders, and maintains that the resulting constipation is due to a lack of innervation.

Fleiner[6] divides constipation into two general classes, the spastic and atonic forms. In the first form spastic contractions in various parts of the intestines cause the feces to be divided, and thus retained, while in the second form there is a general weakening of the muscles of the intestinal walls, with a similar result.

Rosenheim[7] places atony of the bowel among the intestinal neuroses, and believes that in many cases it is due to diminished peristaltic action resulting from deficient innervation, while in other cases it is due to primary weakening of the muscular walls.

Atony of the intestine may be described as that condition in which the walls of the colon have lost their tonicity, and are thus unable to expel the feces at the normal rate. Atony may be primary or secondary. It is *primary* in persons that have accustomed themselves to a diet that does not leave sufficient residue to stimulate intestinal peristalsis, or in whom the opposite condition has been produced by the excessive ingestion of too irritating food.

While the ingestion of excessive quantities of fluid leads to atony of the stomach, a certain quantity of fluid is requisite to aid in softening the hardened fecal masses in the intestine. A diet, therefore, consisting almost entirely of solid food, and containing but little fluid, is likely to produce primary atony of the intestine. Improper hygienic conditions may also lead to the production of the disorder. That those who are subject to sedentary habits and insufficient exercise are prone to become habitually constipated has long been known. The same is true of those who habitually neglect to attend to the calls of nature. Yet it is remarkable that many persons of the most sedentary habits may remain unaffected, while others who indulge in regular exercise suffer with chronic constipation (Henoch).[1]

Not an unimportant part in the production of intestinal atony is the too frequent use of cathartics (Rosenheim),[2] which act more or less as irritants to the bowel and after a time leave it in a weakened condition.

Atony of the intestine may be *secondary* to many other disorders, such as obesity, anemia, and diseases of the heart, lungs, or liver, causing derangement of the circulation. It may also be secondary to diseases of the brain and spinal cord. Hysteria and neurasthenia, according to Dunin,[3] predispose to the disorder.

Atony of the intestine is frequently a sequel of typhoid fever, dysentery, and cholera. It is often due to other diseases of the gastro-intestinal tract,

such as carcinoma of the stomach, chronic gastritis, gastroptosis, intestinal catarrh, enteroptosis, and nervous dyspepsia. According to Peyer,[1] it is not infrequently found as a neurosis secondary to disorders of the male generative organs. The relaxation of the abdominal walls after frequent pregnancies likewise leads to this condition.

Atony of the intestine is frequently found in earliest childhood, and is at times congenital (Henoch[2]). In these cases it may become so marked as to produce actual dilatation. Such a case is reported by Fuetterer and Middeldorpf.[3] The sigmoid flexure of the colon was so dilated as to have a capacity of sixteen liters, and when filled occupied the entire abdominal cavity.

The disorder occurs as frequently in males as in females. The aged, in whom there is a general atonic condition of all organs, are especially subject to it.

The symptom of which patients suffering with intestinal atony complain is marked constipation. This is frequently the only symptom. At times it does not produce much annoyance. Cases have been recorded in which fecal evacuations have occurred at intervals of eight, twelve, or more days without causing any inconvenience. Thus, Henoch[4] reports the case of a woman, sixty years old, who from her earliest years had evacuated her bowels but once every six or eight days, and whose health was in all other respects very good; and Chambers[5] tells of an extraordinarily large and solid colon in a woman who, while in otherwise perfect health, had a movement of the bowel only once every fortnight.

However, the constipation usually becomes very annoying and produces great discomfort. The abdomen frequently becomes distended, giving rise to a feeling of fulness, while the formation of gas causes colicky pains and a desire to discharge flatus. Other symptoms present are headache of a dull character, which may lead to vertigo; loss of appetite; nausea and pressure after eating; pains in the back and loins.

Nervous symptoms are frequently present, such as palpitation of the heart (Kisch[6]), indefinite pains, abnormal sensations of heat and cold, flushes of heat, and sleeplessness. It was at one time claimed that these symptoms are produced by the absorption of toxic materials from the intestine; but Bouchard[7] has shown that fluid feces, being more easily absorbable, are more likely to produce toxic symptoms than hard fecal masses. Katz[1] has recently attempted to prove that auto-intoxication never exists, but that the symptoms occasioned are due purely to reflex nervous changes.

On examination the abdomen is found distended with gas, so that a marked tympanitic sound is elicited on percussion. If the abdominal walls are thin, the configuration of the distended colon may be made out with ease. Usually the abdomen is equally distended, but in cases of partial atony of the intestine the distention is asymmetrical. Large fecal masses can frequently be felt in the region of the sigmoid flexure and descending colon, while the abdomen is sensitive to pressure. The examination of the feces is important in these cases. The fecal masses are usually darker, drier, and harder than normal, and usually consist of large, adherent clumps or cylinders of large caliber.

At times valuable information concerning the condition of the colon can be gained by distending this part with gas. This is best accomplished by the introduction of air into the colon through a soft-rubber tube by means of the bulb of an ordinary spray-apparatus (Runeberg[2]). Under normal conditions the distended part will be found above or in the region of the umbilicus, representing the transverse colon, with the ascending and descending colon on either side. In dislocation of the colon downward, which is a frequent cause of atony of the intestine, the transverse colon is found below its ordinary position, reaching at times as far down as the symphysis pubis, while the ascending and descending colon approach nearer the median line. The colon may not only be dislocated, but it is frequently also considerably enlarged in its transverse diameter.

Of greater importance in the determination of atony of the intestine, as well as of the position of the colon, is a method that has recently been devised by Boas.[3] After the bowels have been moved, warm water is introduced into the colon through a Hegar funnel. Under normal conditions a splashing-sound will not be produced before the bowels contain from 500 to 600 c.c. of water. This splashing-sound is induced by quick movements of the fingers upon the abdomen within an area bounded by a line a hand's-breadth above the umbilicus and another passing through the umbilicus. Under these

conditions the colon can also be mapped out by palpation and percussion. A succussion-sound produced by quick movements of the patient himself can only be made out with difficulty or not at all.

Under pathologic conditions the succussion-sound and the splashing-sound can be generated with but small quantities of water (200–300 c c.), and may reach much lower, at times to the symphysis pubis (*e. g.*, in dislocation of the colon). This method not only shows the position of the large intestine, but also indicates an atonic condition of the colon. As Boas states, this method presupposes that no other abdominal organ, and especially the stomach, can give rise to the splashing-sound. In cases in which the stomach is the source of the sound, as in atony, either the viscus must be emptied by means of a stomach-tube, or the examination must be made in the morning, when the stomach is in a fasting condition. Inasmuch as Boas' statements concerning this method have not received corroboration, I have tested it, and the following embodies the results of my investigation.

Forty perfectly normal persons were examined. In all cases the position of the colon, as thus determined, was verified by insufflation of the bowel with air. The results obtained agree in all respects with the observations of Boas. Under normal conditions from 500 c.c. to 800 c.c. of fluid are needed to obtain the splashing-sound, while a very slight succussion-sound or none at all can be obtained. The lower border of the transverse colon under normal conditions lies at the level of or slightly above the umbilicus, and the upper border from 4 to 7 cm. above this point, the diameter of the transverse colon being from 5 to 7 cm.

In twenty cases of atony of the colon, with marked constipation, the bowels were examined in a similar manner. The results were very striking. In no case was more than 450 c.c. of fluid required to produce the splashing-sound. The succussion-sound was obtained in all cases, and was usually very marked. The lower border of the transverse colon was found below the umbilicus in all cases, at times (in cases of marked enteroptosis) ten or eleven centimeters below, while the upper border was frequently below the normal level. The diameter of the transverse colon was usually between six and nine centimeters. The upper parts of the ascending and descending colon approached the umbilicus in proportion to the degree of enteroptosis. We have thus a simple method of detecting atony, as well as variations in position of the large intestine.

The whole colon is not always equally atonic. We frequently find atony of only the descending colon and of the rectum. This also results in fecal accumulations and marked constipation.

The symptoms of atony of the colon are well illustrated by the following case:

Case XIV, Table II.—K. J., a servant, thirty-five years of age, had complained of marked constipation for the past twenty years. With this exception he has always been well. During the last three years the constipation has been so marked that frequently five or six days pass without a movement of the bowels. Cathartics of many kinds have been constantly employed, and even with these there is but a scant movement. There is a feeling of heaviness and distention of the abdomen. Flatulency and frequent pains from the presence of gas are complained of; at times the pains become colicky. Added to the constipation there is headache, which is usually relieved when the bowels have been opened. The appetite is good. There is frequent palpitation of the heart and general nervousness.

The patient is a well-built man, with a good pulse, and normal heart and lungs. The liver is normal in size; the abdomen is not tender to pressure; the kidneys are not palpable. The abdomen is markedly distended and tympanitic. The functions of the stomach are normal. One hour after an Ewald test-breakfast, small quantities of well-digested gastric contents are obtained, with an acidity of 64; the free hydrochloric acid equals 0.187 per cent. No lactic acid is present. The salol-test shows the motor function of the stomach to be normal. After injecting 300 c.c. of water into the bowel, a marked splashing sound is produced in the region of the ascending, transverse, and descending colon, by gentle shocks with the fingers upon the abdomen. The upper border of the transvere colon is 5.5 cm. above the umbilicus in the median line, the lower border 2 cm. below; the transverse diameter is 7.5 cm. The succussion-sound produced by movements of the patient himself is very marked. The position of the colon as determined by this method is verified by the inflation with air. The stools are larger and darker than normal, but are well formed.

Among the most frequent complications of atony of the intestine may be mentioned enteroptosis (dislocation of the bowel). As is shown in Table II, most of the cases of atony are complicated by this disorder. It is probable that the atony is secondary to the enteroptosis. Another frequent complication is atony of the stomach. It is probable that more than half the cases of atony of the intestine are associated with gastric atony. Of the twenty cases contained in Table II, fourteen were thus complicated.

Case IX well illustrates this association of enteroptosis, gastroptosis, and atony of the stomach as a complication of atony of the intestine.

H. R., fifty years old, a laborer, had malaria and typhoid fever before his twenty-fifth year, but thereafter was in good health until ten years, ago, when he began to complain of gastric and intestinal disturbances. He has had loss of appetite, nausea, a sense of pressure after eating, especially

after the ingestion of fluids, and marked constipation. The disorder has recently progressed in severity, and the constipation has markedly increased, notwithstanding the constant use of cathartics.

The patient is a poorly-nourished man, with pale mucous membranes; his pulse is weak, his tongue coated; the heart and lungs are normal, the liver and spleen not enlarged. The abdomen is tender at several points on the linea alba, especially in the region of the umbilicus. After swallowing but 150 c.c. of water a splashing sound can be produced in the region of the stomach, the greater curvature being 4.5 c.m. below the umbilicus, the upper curvature 8 c.m. above the umbilicus. On inflating the stomach with air, the same boundaries are determined. One hour after an Ewald test-breakfast large quantities of gastric contents are obtained, with an acidity of 62; HCl equals 0.1279 per cent.; no lactic acid is found. While the stomach is quite empty 150 c.c. of water are gradually allowed to run into the bowels; a marked splashing-sound can be elicited in the region of the ascending, transverse, and descending colon, while a marked succussion-sound is also to be heard on quick movements of the patient himself. The upper border of the transverse colon is at the level of the umbilicus in the median line, while the lower border is 6.5 cm. below the umbilicus, the diameter of the colon in the median line being 6.5 cm. The same result was obtained when the colon was inflated with air. The stools are hard and black, the urine normal, containing neither sugar nor albumin.

Another complication found associated with atony of the colon, though less frequently observed, is the condition of membranous enteritis.

Boas[1] has reported such a case, and I have had a similar case under observation for some time.

Case XVII, Table II.—M. G., a mechanic, twenty-nine years old, has complained of marked constipation for many years, and has for the past ten years been required to take purgatives to move his bowels. The stools are always hard and contain mucus, and very frequently during the past year long membranous masses have been cast off, when severe colicky pains are experienced. The patient also complains of loss of appetite, gaseous distention of the abdomen, and great nervousness. The man is rather well built, with normal heart and lungs. The liver and spleen are not enlarged. The right kidney is dislocated to the second degree. Points of tenderness are irregularly noted over the abdomen. By the usual method the stomach and intestines are found dislocated downward and atonic. With but 150 c.c. of water in the bowels marked splashing-sounds and succussion-sounds are produced. The upper border of the transverse colon in the median line is found 3 cm. below the umbilicus, and the lower border 10.5 cm. below, the diameter of the colon in the median line being 7.5 cm. This position of the colon was afterward verified by the inflation of the intestine with air. In the washing large membranous masses were obtained.

Boas believes that in cases like this the membranous enteritis is caused by the abnormal bends and flexures of the large intestine.

The vertigo dyspeptica of Trousseau,[1] which was believed to be due to chronic gastritis, depends in most cases upon atony of the stomach and intestines. I reported such a case in my paper on "Atony of the Stomach."[2] Another case has come under my observation originating in intestinal atony.

Case IV, Table II.—J. L., a male, forty-seven years old, has been suffering from constipation for years, which during the past year has become more severe. The bowels are moved at intervals of four or five days after the use of purgatives. There is constant headache, which has recently become very severe and frequently passes into vertigo. This at times becomes very intense when the constipation has lasted several days, so that the patient is sometimes unable to stand. The vertigo is at once relieved when the bowels are thoroughly evacuated. The appetite is usually good, but when the constipation is very marked the former suffers correspondingly. The patient is a well-nourished individual, with a strong, full pulse. The tongue is coated, the heart and lungs are normal, the liver and spleen not enlarged. The right kidney is dislocated to the second degree. Even after the ingestion of large quantities of fluid (500 c.c.) no splashing sound can be elicited over the region of the stomach. One hour after an Ewald test-breakfast but 35 c.c. of gastric contents are obtained, with an acidity of 66, the HCl equalling 0.184. Seven hours after a Leube test-meal the stomach is found empty. On inflating the stomach with air, it is found dislocated slightly downward, the lesser curvature being 5 cm. below the ensiform cartilage in the median line, the greater curvature 2 cm. below the umbilicus. While the stomach is empty 100 c.c. of warm water are thrown into the bowels, and marked splashing-sounds and succussion-sounds are produced. The upper border of the colon in the median line is at the umbilicus, the lower border 7.5 cm. below, the greatest diameter of the transverse colon being 7.5 cm. The urine is clear, and contains neither sugar, albumin, nor casts.

Intestinal catarrh and ileus paralyticus may also be mentioned as complications of intestinal atony. Ileus paralyticus may arise when long-continued atony has passed over into paralysis of the bowels. Under these circumstances the advance of feces is arrested and the symptoms of intestinal obstruction are induced.

Large fecal tumors are often formed as a result of atonic conditions of the bowels. These may

[1] Boas: Loc. cit., p. 84.

[1] Trousseau: "Vertigo Dyspeptica," Gaz. des Hôpitaux, 1862.

[2] Loc. cit., p. 12.

become so large as to simulate tumors of other organs. According to Griessinger[1] forms of mental derangement may result from the chronic constipation found in atonic conditions of the bowels, which may even lead to grave forms of hypochondria.

Atony of the intestine must be differentiated from other disorder of the bowels leading to chronic constipation. Among these may be mentioned entero-spasm (that is, a spastic condition of the colon), chronic colitis, and dilatation of the colon.

From entero-spasm atony is diagnosticated by the peculiar character of the stools. In the former the stools are usually pencil-shaped in form. In some, small amounts only are passed; in others the stools are abundant, but always of small caliber. In these cases the splashing sounds and succussion-sounds cannot be produced by the method of Boas with small quantities of fluid.

From chronic colitis, atony of the intestine is also distinguished by the condition of the stools. In chronic colitis they are found constantly and intimately intermingled with or surrounded by layers of mucus, which at times may be so small in quantity that only a microscopic examination will reveal the true condition. With small quantities of fluid, according to the method of Boas, neither splashing-sounds nor succussion-sounds can be produced. At times the two conditions, atony and chronic colitis, may coexist.

From dilatation of the colon, atony may usually be diagnosticated by a careful rectal examination. In most cases of dilated colon, some rectal obstruction will be found which will be recognized as the cause of the dilatation. That atonic dilatation of the colon does occur is, however, well known. A case of this kind has been recently reported by Walker and Griffiths[2] in which an enormous congenital dilatation was found in a boy, giving rise to great abdominal distention, tympanites, etc.

The treatment of intestinal atony depends upon its cause. If the condition is secondary, the treatment must be directed to the primary disorder.

Chronic constipation is the symptom that occasions most annoyance, and special attention must be directed to it. In all uncomplicated cases of atony of the colon the condition can be successfully relieved by simple measures. The hygienic and dietetic treatment is highly important. Inasmuch as sedentary habits predispose to this disorder, exercise is of some value in many cases. This should consist in walking, as well as in gymnastics in which movements of the trunk play a prominent part.

Such foods are ordered as stimulate intestinal peristalsis. In this class are included substances that furnish a large quantity of undigested residue, such as fruits, vegetables, salads, Graham and rye breads. When there is no special contra-indication (such as gastric atony), large quantities of cold water taken before breakfast may be serviceable.

There are certain natural mineral waters which are sometimes of great value in the treatment of intestinal atony unaccompanied by atony of the stomach; the Glauber salt waters belong to this class. The waters of Marienbad are considered of great value for this purpose, especially in the obese; but the saline waters, Kissingen Rokoczy, are sometimes preferable. However, as many cases of intestinal atony are accompanied by atony of the stomach, the use of large quantities of water in these cases should be very restricted.

Persons suffering with intestinal atony should avoid the use of food that tends to constipate. In this class may be especially mentioned red wines, tea, and rice.

The systematic employment of abdominal massage is of great value. There are but few uncomplicated cases of intestinal atony in which the constipation does not yield to this form of treatment. In very persistent cases the manipulation must be practised daily, or on alternate days at least, for from eight to twelve weeks. To be effectual the movements must be deep.

Abdominal massage is much assisted by electricity; by the external application of moderately strong faradic currents good effects are usually obtained; or the faradic current may at times be applied internally, one electrode being placed in the rectum, the other on the abdomen. When the galvanic current is used the rectum is filled with water before the negative pole is introduced, the positive pole being placed upon the abdomen.

In cases in which massage and electricity cannot be employed excellent results are frequently obtained by injections of large quantities of oil, as recommended by Fleiner.[1] When the conditions insisted on by Fleiner are fulfilled the injections rarely fail. In a large number of cases in which I have employed these injections for the treatment of this form of chronic constipation they rarely proved unsuccessful. The regulations to be fulfilled are: 1. Only the very purest oil should be employed; olive-oil is the best. 2. Large quantities of the oil (from ten to fifteen ounces), heated to the temperature of the body, must be injected while the patient

[1] Griessinger: Pathologie und Therapie d. psych. Krankheiten, 3te Auflage, S. 221, 236 und 301.

[2] Walker and Griffiths: "Congenital Dilatation and Hypertrophy of the Colon fatal at the age of Eleven Years," British Medical Journal, July 29, 1893, page 230.

[1] Fleiner: "Ueber die Behandlung der Constipation und einige Dickdarmaffectionen mit grossen Oelklystieren," Berliner klin. Wochenschrift, January 16 and 23, 1893, Nos. 3 and 4.

is resting on the back with the pelvis raised. 3. The injections must be given carefully and slowly, so that no air enters the colon. When air is introduced severe colicky pains are frequently produced and the oil is immediately ejected. 4. The oil must be retained in the bowels for several hours; for this reason it is best for the patient to remain in the reclining position for several hours after the injection has been given.

When the injections of oil and the other methods just mentioned cannot be employed, injections of other fluids, such as warm water, cold water, glycerin, may prove serviceable. The introduction of glycerin suppositories into the rectum or the application of powdered boric acid to the mucous membrane of the rectum sometimes gives relief.

The employment of cathartics is in most cases to be deprecated. Inasmuch as patients become quickly habituated to remedies of this kind and their effect gradually wears away, larger and larger doses become necessary. When cathartics must be given the simplest are the best, and the various preparations of cascara sagrada seem to me to head this list. Pills of strychnin sulphate or the extract of nux vomica with belladonna are to be highly recommended to strengthen the relaxed condition of the bowels.

THE MILD CHARACTER AND THE DIMINISHED PREVALENCE OF SYPHILIS, AND THE INFREQUENCY OF VISCERAL SYPHILIS.[1]

By J. H. MUSSER, M.D.,
of Philadelphia;
Assistant Professor of Clinical Medicine in the University of Pennsylvania; Visiting Physician to the Philadelphia Hospital and to the Presbyterian Hospital, etc.

I am fully aware of the want of precision of the statements in this paper that should attend all scientific communications. For reasons that will be briefly considered later, such precision could not be obtained. It is unfortunate that we must deal in generalities, but the tide of thought may be turned in the direction indicated by these lines, and precision sooner or later be attained. This paper is presented with the object of eliciting discussion, so that, if possible, we can carry with us, if desirable, more definite notions of the prevalence of the disease and of the virulence of its manifestations.

The frequency in a community of a disease of the character we are considering can only be determined positively by compulsory notification. In the absence of such notification, we must resort to the statistics of the hospitals and to the records of physicians in private practice. The former do not tell the story correctly, because too many individuals are engaged in the make-up of the statistics. That uncertain quality, the "personal equation," is one of the many disturbing factors that make such data unreliable. Moreover, the victim of a disease like syphilis, which presents so many "ups and downs," may be treated at different times in the same institution during the same year, or at various institutions during that period.

The records of physicians in private practice would likewise be misleading. The tendency of syphilitic patients to see more than one physician, the choice depending upon the organ or structure at the time the seat of the disease, is one factor. Again, the class of practice that engages the attention of the individual physician would modify his statistics. The specialist on venereal diseases sometimes shudders at their apparent prevalence in the community, while the general practitioner observes but few cases in a corresponding period. Then, too, a man at fifty must not decide upon the frequency of a disease because he sees more than he did at twenty-five.

In short, there is no definite quantity upon which to base our calculations. This difficulty may in part be overcome by taking a definite class of men who are under the observation of a corps of students guided by the same definite purpose, both classes remaining as more or less fixed quantities. The statistics of the Army and Navy are therefore reliable up to a certain point. They are not, however, an index of the ravages in a community.

Another factor that does not fluctuate may be found in the records of the hospitals and dispensaries that treat venereal diseases alone. If one only of each existed in a city, a fair idea of the prevalence of the disease could be obtained. Usually this is impossible; especially is this so with dispensaries, for the patient wanders from one to another at his own option as fancy or convenience dictates. Many other factors also, as the movement of population, cause a variance in the attendance of patients upon a particular dispensary.

The nearest approach to the ideal definite quantity is to be found in a community that has but one hospital for the treatment of syphilis. Even here fallacies enter, and we can only judge of the frequency of the disease by inference, for the class attendant upon the hospital constitutes only a portion of the total number that may be infected.

Obviously, therefore, we can only come to that which approaches a conclusion by the expression of individual impressions. Scientific definiteness of statement, it is to be deplored, cannot be obtained. If such impressions tally with the statistics of a hospital situated under the circumstances indicated, they are all the more trustworthy.

Notwithstanding the increased scope of view,

[1] Read before the Association of American Physicians, at Washington, D. C., May 31, 1894.

and the occurrences of fallacies, I am firmly imbued with the impression that there is less syphilis in Philadelphia than there was ten or fifteen years ago. It is certain that the disease does not come under observation as frequently, either in private or hospital practice, as in former years. Does this tally with hospital-statistics that have some impress of definiteness?

In Philadelphia the indoor treatment of syphilis with lesions that render the disease communicable is limited to the Philadelphia Hospital (Blockley). To the wards of this hospital are admitted those of the poorer classes that are victims of the disease. It follows that any statement concerning the prevalence of syphilis obviously applies only to this prevalence among the poorer classes. The development of the disease is, however, more favored by the conditions that surround these classes. Any fluctuation in the prevalence of the disease among them is nevertheless a tolerably fair index of its frequency in a community.

The percentage of the cases of syphilis treated in the Philadelphia Hospital is indicated by the following table:

Per Cent. Syphilis in Hospital for Periods of Five Years—1864 to 1893 Inclusive.

1864 to 1868 = 6.68 per cent.	1879 to 1883 = 4.26 per cent.
1869 to 1873 = 4.56 "	1884 to 1888 = 3.76 "
1874 to 1878 = 3.36 "	1889 to 1893 = 3.05 "

It is thus seen that in a period of twenty-nine years the reduction in the percentage of cases of syphilis is more than one-half, and this in face of the fact that the population of the community from which the cases are drawn has increased fully 35 per cent. in the three decades, and that, moreover, this reduction in percentage would be still greater if the other wards of the hospital increased in a ratio corresponding to the increase of population of the city of Philadelphia. In 1864, 5815 cases were treated in the hospital, whereas the number had only increased in 1892 to 7942 cases, a ratio of increase far below the increase of the sick poor of the population. This increase did not occur, because five new hospitals were built and all of the old hospitals were enlarged, furnishing shelter for the sick that otherwise would have sought the Philadelphia Hospital.

The *cause* of this diminished prevalence of syphilis can only be a matter of speculation until we have more satisfactory knowledge of the nature of the specific virus and of its biologic properties. It is fair to presume that habits of greater cleanliness among the public form one large causal factor. Then, too, the more modern methods of treatment, which lessen the duration of the contagious period of the disease, contribute to this decline. It is furthermore not stretching the imagination to any great extent to urge the probability either that the soil is less favorable for the development of the disease, or that the activity of the virus is attenuated.

It must, of course, be remembered that the "war-period" had much to do with the prevalence of syphilis in the decade from 1864 to 1874.

The mild character of syphilis. I have had forty-eight cases of syphilis throughout its course, under observation as family practitioner for periods of ten years. Three are in women that have married and have borne children. In two of these the children presented symptoms of inherited syphilis, but have grown up healthy. Other children in perfect health were subsequently born to the parents. All of these cases I believe are cured. None ever presented grave lesions of syphilis. The only case of death from syphilis that I saw, barring aneurisms and other vascular lesions of this disease, was one in which meningitis developed in a young man in the practice of Professor Wood.

If we compare the present records of the venereal wards of the Philadelphia Hospital with those of twenty and thirty years ago, we find the most marked improvement. Formerly, grave ulcerous lesions were common; now they are the exception. The "syphilitic cachexia" was frequently seen; now it is extremely rare.

I had expected to show from a study of all cases of syphilis in the hospital a decline of the tertiary varieties of the disease. Such decline has occurred, and, in view of the facts previously mentioned regarding the increase of accommodations of other institutions for such patients, is not without significance. From 1864 to 1868, 3 per cent. of all cases in the hospital were recorded as tertiary, visceral, or nervous forms of syphilis. All forms of internal syphilis are included. The diminution was one only of moderate degree—from 1868 to 1873 to 2.25 per cent.; from 1874 to 1878, 1.95 per cent.; from 1879 to 1883, 2.2 per cent.; from 1884 to 1888, 2.65 per cent.; from 1888 to 1893, 2.45 per cent. The decline is only a fractional one, but even no decline in per cent. would mean a diminution in amount.

I believe there was less tertiary syphilis than the records indicate. In one year the records of the nervous wards showed sixty-nine cases of syphilitic hemiplegia; in another year the cases of this character were less than six. It looks as if the diagnosis was made in accordance with the bias of the observer. The small amount of tertiary and visceral syphilis seems to indicate a lessening of the virulence of syphilis. This is substantiated by the accounts of the disease given by writers of forty or sixty years ago, and by the statements of physicians whose experience bridges the epoch just mentioned. In the Presbyterian Hospital we have treated in the medical wards 5000 cases. Of that number thirty

cases were diagnosticated as tertiary syphilis; eleven cerebral; two spinal; two hepatic; four laryngo-pharyngeal; a total of forty-nine cases. Certainly if the disease was common and severe, more cases would have resorted to this institution.

Syphilitic disease of the organs of the thorax and abdomen is included, with the exception of syphilis of the bloodvessels, endarteritis. Here, again, older writings are full; modern writings are the echoes apparently of the past. The experience in the Presbyterian Hospital is a case in point of their infrequency. In a series of three hundred and thirty autopsies which I have conducted, the visceral lesions of syphilis (other than vascular) occurred but once. In private practice I have had but two cases (elsewhere reported) of visceral syphilis outside of the nervous and vascular systems. Are we not justified in asking: If pulmonary and other forms of visceral syphilis are rare, is it not possible that the so-called syphilitic lesions of the arteries and nervous system are due to other causes?

The statistics that I could consult are unreliable, I regret to say, and any information they may possess is buried in such a manner in the notes of the autopsy as to be unavailable.

Granting the mild character of syphilis and the infrequency of visceral forms, are we warranted in considering the syphilitic process a factor in the pathology of vascular and nervous syphilis? I believe that visceral syphilis has been common in the past, or else was mistaken for the lesions of tuberculosis. I believe that it is at present infrequent, without being able to give definite data. Should there not be a similar decline in the frequency of vascular and secondarily (for there is usually a primary endarteritis) nervous syphilis?

Résume. In the Philadelphia Hospital, the only institution in Philadelphia in which early syphilis is treated, there has been a progressive diminution in the number of cases of syphilis, notwithstanding the increase in the population of the community, and despite the fact that the statistics were begun just after the war, at a time rife with such diseases. Syphilis is at present a mild disease. Tertiary manifestations are not common. Visceral syphilis is rare.

INOCULABILITY OF ECTHYMA.[1]

By J. H. McCORMICK, M.D.,
of Washington, D. C.

When one sees an inflammation of any kind in this iconoclastic age of ours he asks if it is infectious or contagious, and if it is due to a specific organism. This has been the case with almost every affection of the skin, with the exception of ecthyma, and this seems, in a great measure, to have escaped this inquiry. As most authors describe the disease as non-specific and non-infectious, and as German authorities, under the lead of Hebra and Kaposi, deny the existence of the disease as an affection, *sui generis*, believing it to be eczematous in character, and thus considering it a symptom and not a disease, and as the clinical picture of a typical ecthymic eruption is seemingly at variance with both of these claims, it was determined to seek the solution of the problem at the first opportunity by a series of experiments in order to ascertain whether the former or the latter proposition was true.

In the early spring of 1892 the following case appeared at the Johns Hopkins Hospital, exhibiting such a typical eruption and such an interesting history that it seemed to be the case above all others for the investigations in question.

G. E., thirty-five years old, by occupation a book-keeper, of slight build and medium height, and of a decidedly anemic appearance, was, several weeks before consulting us, called upon to care for his employer's horse, in the absence of the regular hostler, a business with which he was unfamiliar. He noticed several "sores" upon the animal's leg, and treated them with carbolic lotions. About a week afterward he noticed five or six pustules upon his own right leg. These pustules, situated each upon a large dark-red areola, broke down, and at the end of two or three days formed dark-red or brown crusts. The itching was quite severe, and at the time of his admission to the hospital there were seven or eight large, elevated, hard, dark-brown or brownish-black incrustations, about the size of the finger-nail, situated upon and deeply imbedded in a deep-red base, which completely surrounded them; upon removal of the crusts, a thin, yellowish, sanious pus exuded; the pain and itching were considerable; the whole presented the appearance of a typical ecthymic eruption, showing that an active inflammatory process had taken place.

The patient was inoculated in three different sites upon the posterior surface of the left leg, and was told to return in three days; at the end of that time the places where the inoculations were made showed a typical eruption, with the exception that the pustules were not quite so large and indurated as those from which they were taken, and it is interesting to note that in no other spots did the eruption appear except where the inoculations were made.

At the second visit, two patients, one suffering from lupus the other from seborrhœa sicca, consented to be inoculated, and for sake of convenience were designated A and B.

A was inoculated upon the right leg from the right leg of the original patient, and B upon the left leg from the left leg or induced case; at the end of three days the eruption appeared in every place thus treated.

The virus was transferred from the left leg of B to the left of A, and from the right of A to the

[1] Read before the Medical Society of the District of Columbia, April 18, 1894.

corresponding limb of B, and when the resulting lesions made their appearance, as they promptly did at the end of three days, they were transferred to either arm of the original patient, and in every case the eruption appeared more or less marked in every site thus treated.

By reason of the unavoidable absence of Dr. Gilchrist, who so kindly assisted me in the first experiments, we were unable to make a bacteriologic examination to determine whether there were specific ecthymic bacilli or some other present.

Dr. Hyde, pursuing the same course as Kaposi, claims that ecthyma is not a distinct disease, but is due to some common septic bacteria, and that the eruption is but one of the many manifestations of eczema; yet he thinks that the term ecthyma should be retained, and should be used for convenience, because the lesion is quite characteristic, and thus the disease is described meagerly, or not at all, by German authorities; while, on the other hand, just as competent observers have recorded 726 cases out of a total of 123,746, noted in the *American Statistics of Dermatology*. Stelwagon records 23 cases out of 4200 cases of skin-disease seen by him at the Philadelphia Hospital for Skin Diseases, covering a period of ten years, from February, 1880, to November, 1890. It is probable that if the affection were a mere eczema it would occur more frequently than the statistics show. As to its powers of infection, James S. Rankin, of Segowlie, Bengal, describes ten cases in which the disease was transmitted from one to another. Three children played with his own child, aged six years, who became infected with the same trouble from which they suffered, and which he stated was, or closely resembled, ecthyma. The child in turn infected his mother. Upon investigation it was learned that these children had just returned from the indigo-district, where they had come in contact with four or five others who were afflicted in the same manner, and the eruption was attributed to the irritation caused by the liberation of ammonia in the indigo-factories where the latter cases worked.

As to the inoculability of ecthyma, Vidal, in 1846, demonstrated its auto-inoculability by transferring the virus from the leg to the forearm.

It is not the province of this paper to discuss the question of treatment, but in passing it may be interesting to state that some trial was made with a combination of antipyrin and sodium bicarbonate, based upon its reputed resemblance to quinin, and the property of the latter to allay or arrest the process of pustulation. While the conclusion is not warranted that it always is efficient, yet the influence of the combination was sufficiently marked to justify further investigation.

From the facts as stated the following recapitulation may be made as a basis for future investigation:

First. *a.* By direct experimentation.

(1.) Vidal, in 1846, demonstrated the auto-inoculability of ecthyma.

(2.) The author, in 1892, demonstrated the auto-inoculability and the inter-inoculability of the disease.

b. By presumptive evidence James S. Rankin, in 1883, demonstrated its infectiousness.

Second. As to the existence of ecthyma as a disease, *per se*, *a.* Hebra, Kaposi, Hyde, et al., claim it to be the manifestation of an eczema or dermatitis, due to a simple septic bacillus.

b. Most authors claim it to be non-specific, but a distinct disease.

Third. As to its power of infection.

a. Positive: Rankin demonstrated its infectiousness.

b. Positive: Vidal and the author demonstrated its infectiousness by artificial means.

c. Negative: Most authors claim it to be non-infectious, based upon their failure to observe it as such.

Fourth. As to the presence of a specific ecthymic bacillus.

a. Most or all authors claim that there is none.

b. In the foregoing observations we failed, by accident, to note this particular fact.

Fifth. The following points, for one or another reason, were not noted:

a. The presence or absence of a specific ecthymic bacillus.

b. The presence or absence of bacteria of any kind in the patient.

c. The presence or absence of bacteria of any kind in the eruption upon the horse.

Sixth. The results, while not conclusive, because based upon too few experiments, seem to warrant the following conclusions:

1. That ecthyma is auto-inoculable.
2. That ecthyma is inter-inoculable.
3. That ecthyma is infectious.

a. From animals to man.

b. From man to man.

1225 L Street, N. W.

CLINICAL MEMORANDA.

THREE AMPUTATIONS OF THE THIGH—TWO IN THE UPPER THIRD, ONE AT THE MIDDLE.

By JOHN W. ROSS, M.D.,
SURGEON, U. S. N.

Case I.—Lewis Hart, a negro, seventeen years old, of Yellow River, Santa Rosa County, Fla., was brought to me March 24, 1888, with the right knee and ankle disorganized by suppurative tuberculous disease of seven years' standing. All the structures concerned in these joints were involved; the knee was dislocated outward; pus was escaping by seven or eight fistulæ in the thigh

and leg; the lower end of the femur was softened and breaking down. There was great emaciation, profound anemia, extreme debility, difficulty in deglutition, loud anemic cardiac murmurs, but no organic disease of vital organs.

I decided to amputate as soon as the patient could be built up sufficiently to stand the operation.

On March 28th, the patient, showing no signs of improvement, but rather the reverse, I concluded to operate at once. Captain M. C. Wyeth, U. S. A., Post-Surgeon at Fort Barrancas, willingly consented to help me, although he thought that the patient would die from the anesthetic, as his heart was acting badly. He administered the ether, preceding it by a small drink of whiskey, and the operation was quickly done, Apothecaries Purden and Waggener, U. S. N., and Nurse John Kelly assisting us. On account of the unhealthy state of the soft parts, an irregular flap-operation, approaching the circular, was done, two fistulous openings being unavoidably included in the longer anterior flap. The femur at the point of section, at about its center, was hardly more than a circular shell of bone, with a large medullary cavity.

The patient emerged from the anesthesia with very little life in him, but was kept alive for a few days by frequent small quantities of liquid food, digitalis, and stimulants. After that he began to gain strength, and continued to do so, though very slowly. The vitality of the tissues was so low that it was impossible to get even an attempt at primary union of the flaps, and the stump had to be treated as an open wound. Whenever it was closed pain would come on and the temperature would rise. The flaps were kept as aseptic and in as good a position as possible, and at the end of about three months the patient went home with a good stump and in fair general health.

After reaching home he grew fat and hearty, and being unusually intelligent acquired a fair education, writing me occasionally very creditable letters.

Subsequently the same trouble that had destroyed the knee and ankle unfortunately reappeared in some of the lower costo-vertebral articulations, and the patient returned to me with an abscess to the right of the spine in the lower dorsal region. This was opened and cleaned out, and for about two years since there has been no advance of the trouble and the general health has been good.

Case II.—Captain W. C. Gorgas, U. S. Army, Post-Surgeon at Fort Barrancas, who took a prominent part in the operation and after-treatment, has kindly given me a copy of his record of the following case:

"Thor Christiansen, a Swedish sailor, eighteen years old, in February, 1890, fell, in Pensacola Harbor, from the mast of his ship to the deck, striking on the head of a belaying-pin, driving it through the upper third of his left thigh and breaking the femur at this point.

"He was taken to the Marine Hospital at Pensacola, and attempts were made to save the limb, but suppuration set in and the patient went from bad to worse.

"I first saw the patient July 13, 1890, in consultation with Dr. J. W. Ross, U. S. N., and Dr. Anderson. The lower fragment at this time protruded through the skin, and the upper one was about to come through, both communicating with a pus-cavity that held about a pint. The man suffered great pain, any movement causing him to cry out. The emaciation and debility were greater than I have ever seen in a person who recovered. Indeed, I thought it probable that he would not survive the night. I estimated at the time that he had about three square feet of bedsores, the largest, that over the sacrum, covering fully a square foot, and laying the bone bare. Every point of pressure was bare, elbows, scapulæ, ribs, iliac bones, etc., and the pressing bone was bare in many of these places. There was no albumin in the urine, and all other organs were healthy. I was inclined to think that the patient would die in the course of the next twenty-four hours; I was quite sure that he would not survive operation. This was the opinion of all who had seen him.

"Dr. Ross, having had a somewhat similar case before, urged immediate amputation, in which I supported him with many misgivings. Dr. Ross amputated at the point of fracture, making a circular skin-flap, and slitting up the flap to get out the dead bone. A short piece of femur was left *in situ*, the idea being to subject the man to as little shock as possible, and to disarticulate at the hip-joint a few days later, after he had somewhat recovered. Great care was given to asepsis during the operation. The patient suffered profoundly from shock for several hours, and it was only by steady care and stimulation that he survived. He began to gain from the day after the operation, and we kept deferring the second operation till we saw that it was not needed. He was moved to the military hospital at Fort Barrancas on the 21st.

"Improvement was rapid and steady, and by September 22d he was walking about on crutches. He left the hospital in December, with all of the bedsores healed and the stump in good condition.

"What so impressed me in this case was the fact that a patient so weak and debilitated could recover from any operation. In future I shall not hesitate to operate on a patient, with otherwise healthy organs, on account of debility, unless he is actually *in articulo mortis*. After this case it seems to me that it can never be too late to operate on such a patient."

Having been called in consultation by the surgeon of the hospital, I saw Christiansen first on July 10th, three days before the operation and about five months after the reception of the injury. He was a mere shadow and was expected to die at any hour. The lower end of the upper and the upper end of the lower fragment were widely separated, with several pieces of dead bone and a large pus-cavity intervening. The surgeon, after having tried many ingenious contrivances for keeping the bones in juxtaposition, had abandoned all hope of union, and was doing what he could to diminish suffering. As there was no other earthly hope, and as I had seen a very similar case saved by it, I advised immediate operation.

On July 12th the patient collapsed, and it was thought that the end had come. After he had reacted the surgeon telegraphed me to come up and amputate.

On the next morning, July 13th, Dr. Gorgas, Dr. Anderson, and I, assisted by our apothecaries and stewards, operated in the manner described.

Once during the operation and once immediately afterward life appeared about extinct, but with external

heat, stimulants hypodermatically and internally, and his wonderful vital tenacity, the patient survived. Apothecary (now Dr.) Richard Waggener staid by him until the next day, keeping him warm, nourishing him, and stimulating him *per os* and hypodermatically with whiskey, digitalis, and atropin. On the following morning Dr. Anderson told me that the patient would surely have died during the night but for Waggener's faithful and skilful care. As the attendants in the hospital were overworked with other patients, one of the navy or army attendants nursed Christiansen night and day for nearly a week, at the end of which time he had gained a little strength and was comparatively comfortable. On July 21st Dr. Gorgas, in great kindness, sent an ambulance and took the patient to the army hospital, where there was a full corps of attendants and few patients. There he was nursed like a child back to health, the great difficulties being to heal the bedsores and teach him how to walk, as the muscles had atrophied and apparently disappeared.

Finally, by December, being perfectly well and sound, he went back to his home in Wexio, Sweden.

Some months later he sent me a grateful letter, telling me that he was strong and robust, asking advice regarding an artificial leg, and sending his photograph, which showed him to be in perfect health.

In the following case the operation was not done by me. I am responsible for it, however, as but for my persistency it would not have been performed. It is reported here, because it conveys the same lesson, *nil desperandum*, as the two foregoing, and because of its striking resemblance to one of them. But for my experience with this case I should not have advocated or done the operation in Case II.

Case III.—George William Ritchie, an ordinary seaman-apprentice on the U. S. Flagship *Hartford* about nineteen years old, on October 24, 1884, fell from aloft on the *Hartford* in the bay of Callao, Peru, striking the ratlines and landing on the grating of the Hotchkiss gun, sustaining a compound, comminuted fracture of the upper third of the left femur, a fragment of bone projecting through the external wound.

On October 28th he was transferred ashore to the Guadalupe Hospital, Callao, where he passed out of the hands of the U. S. Surgeons.

The *Hartford* sailed away not long afterward, and I being attached to the U. S. S. *Onward*, at Callao, was requested to look out for the boy. He seemed never to have recovered fully from the shock of the injury, and had gone along pretty rapidly from bad to worse. At the end of about three weeks he was in very much the same condition as was the boy Christiansen (whose case has been described) when first seen by me, except that he was less emaciated and the bedsores were not so bad. The wound was bathed in pus, and the broken ends of the upper and lower fragments movable and overlapping for several inches, with two or three pieces of broken bone hanging to them. There was high fever (apparently hectic), profound prostration, delirium, and intense suffering. A skilful diagnostician who examined him carefully, thought that pyemia had set in, involving especially the lungs.

As death was certain and imminent without it, I endeavored to get the visiting surgeon of the hospital, Dr. Távara, to remove the limb. He declined on the ground that it would be entirely useless, that the boy would die whether he amputated or not, and that it would injure his private practice to have the patient die during or immediately after operating upon him.

At about this time the U. S. Steamship *Wachusett* came to Callao, with Surgeons W. H. Jones and W. R. DuBose, U. S. Navy, on board. These gentlemen went with me to see Ritchie, and agreed that death was inevitable without amputation. I also got Dr. Campion, a very able English surgeon of the Pacific Navigation Company, in charge of their hospital at Callao, to see Ritchie, and he shared the same opinion. I then brought about a meeting of these surgeons, Drs. Jones, DuBose, Campion, and Távara, for a careful consideration of the case. Dr. Campion thought that amputation could do no harm and would greatly diminish the patient's suffering. Dr. Jones had slight hope that it might save the patient's life, and remarked that anyhow we might just as well kill him as to let him die by inches. Dr. DuBose thought that the only shadow of a chance for the patient's life lay in amputation. Dr. Távara considered that amputation would shorten the patient's life, that he did not like to operate in such hopeless cases, and that it would injure his reputation as a surgeon for Ritchie to die during or as the result of the operation. I said that the patient was a red-headed Scotch lad, with lots of vitality, and that if we would rid him of that thigh, with its terrible pain and discharge, I believed he would get well. I proposed that if Dr. Távara would go ahead and cut the limb off we would all assist him in the operation and take the whole responsibility. The other surgeons supported me in this, and Dr. Távara yielded.

On November 9th, the day following our conference, I believe, we met at the Guadalupe Hospital, and assisted Dr. Távara in amputating in the upper third of the left thigh.

The very next day the patient was decidedly improved in every way, and from that time went straight along to recovery.

During the following year I met Ritchie in New York City, getting fitted with an artificial limb. He was in fine health, and seemed almost as active on his one leg and crutch as the average man is on two legs.

In these three cases, all of the kind that have entered into my experience during the past ten years, three lives were saved, but had only one been saved the amputations, with all their trouble, responsibility, etc., would have been amply justified. They are reported with the hope that the results may cause other surgeons to operate under similar circumstances when they would not otherwise do so. Obviously the lesson they convey is of much wider application than to amputations, and covers all cases in which without operation death is certain, and when with it the slightest chance for life is afforded. It is not an agreeable thing to have a patient die upon the table, or to feel that an operation has been the immediate cause of death, and that the surgeon's reputation may temporarily suffer thereby, but it is the surgeon's duty to put himself in the patient's place, and do unto him as he would wish to be done by. Human life is too sacred for any chance, however small, of saving it to be thrown away. In such cases, even when the patient

does not survive, he is almost certainly delivered from much suffering.

I remember seeing in Bellevue Hospital, New York, about twenty years ago, a woman who for some iniury of the leg had been urged to submit to amputation above the knee. She refused operation until she saw that she was about to die, and then begged with tears to have it done. Then the surgeons would not amputate, believing that it was too late, and within a day or two the woman died. I have often thought since that had they operated promptly as soon as she gave her consent her life might possibly have been saved.

In the foregoing cases no unusual operative skill was employed, nothing more than any well-equipped surgeon of moderate experience might command.

A study of these three cases has strengthened an opinion long held by me, that the danger of shock in modern operative surgery is overestimated. May not much of the dread of it have come down to us from the pre-anesthesia days when there was so much suffering from pain and fear? May not much that we attribute nowadays to shock be due to loss of blood or to too energetic administration of anesthetics? I can testify from personal subjective experience that the shock of being knocked down by an anesthetic, as it is frequently administered, is very great indeed, extremely like that of a heavy blow on the top of the head.

Our plan here (the Government Reservation, near Pensacola, Fla.) is in the great majority of cases, both obstetric and surgical, to begin with chloroform given in small quantities very gradually until the patient sinks into an apparently natural sleep, and then the sensibility of the respiratory mucous membrane being obtunded, substituting the more irritating but less dangerous ether, to maintain the anesthesia with the latter. This method costs a little more time and trouble, but we are satisfied that it pays well. In our work here we have given chloroform and ether to several hundred patients without any approach to an accident from the anesthetic. As Dr. Gorgas expresses it, "We chloroform the patients in order to give them ether."

EXCISION OF THE GASSERIAN GANGLION.[1]

By R. W. STEWART, M.D., M.R.C.S.,
SURGEON TO MERCY HOSPITAL, PITTSBURG, PA.

The first operation for the removal of the Gasserian ganglion was performed by Rose, an English surgeon, in 1891, since which time it has been performed about forty times. As neither the number of cases that have been operated upon nor the duration of time that has elapsed is yet sufficient to thoroughly establish the value of the operation, any statistical material that can be added to that already published cannot but be of value.

The following case is interesting, as it illustrates, in addition to the operation named, the results of two others undertaken for the relief of tic douloureux:

Mrs. H. R., forty-eight years old, married, having four children living and healthy and three dead, came under observation May 27, 1892. She had had good health until about twelve years before, when she began to suffer from neuralgia affecting the right superior maxillary nerve, the most sensitive point being the mucocutaneous border of the upper lip on the right side. The pain was paroxysmal, and was induced by the slightest irritation of the upper lip and buccal mucous membrane on the affected side. Eating and drinking were particularly prone to excite a paroxysm of pain. While the pain invariably started from the second branch of the fifth nerve, it frequently radiated along the other branches of the nerve. During the period of the twelve years referred to, the patient had tried all kinds of remedies without any relief. In April, 1890, Dr. A. M. Cook, of Newcastle, Pa., excised the superior maxillary nerve external to the infra-orbital foramen. This operation afforded relief from the pain for a period of eight months, at the end of which time it returned in a more violent degree than ever.

On May 31, 1892, I operated on the patient at the Mercy Hospital, removing the superior maxillary nerve as far back as the foramen rotundum, together with Meckel's ganglion. The operation was performed after the method of Carnochan, as follows: A triangular flap was raised, its base being upward, and the center corresponding to the infra-orbital foramen. The nerve, as it emerged from the foramen, was freed from the surrounding tissue, and a fixation-ligature was thrown around it. A stout gouge-chisel was next used to open the anterior wall of the antrum, into which an opening was made corresponding with the foramen, and large enough to permit of the introduction of the finger. The nerve was easily traced along the roof of the antrum, and was used as a guide to the posterior wall of the antrum, through which, in turn, an opening was made into the spheno-maxillary fossa. Through this opening an aneurism-needle was thrust, keeping close to the nerve until the anterior surface of the sphenoid arrested its progress. The needle was now rotated in a semi-circle, tearing the nerve apart at the foramen rotundum.

It was found necessary to break the floor of the orbit from within the antrum, in order to liberate the nerve from its bony channel. The nerve was then readily withdrawn, having attached to it the ganglion of Meckel. Hemorrhage during the operation was not troublesome, and was readily arrested by packing the wound with iodoform-gauze.

On June 2d the iodoform-packing was removed and the flap sutured in position. No constitutional disturbance or pain had been felt since the operation. On June 7th the patient was discharged from the hospital, the wound being entirely healed. There was entire absence of pain, but complete anesthesia of the parts supplied by the superior maxillary nerve and Meckel's ganglion. On January 28, 1893, the patient reported that there had been no return of the pain. The parts supplied by the second branch of the fifth nerve were only slightly sensitive.

Mrs. R. remained free from pain for about two years following the operation described. Then the pain gradually returned, and on March 21, 1894, she came to Pittsburg to consult me. She was at this time in a truly pitiable condition. The neuralgia was not only as severe as before the previous operation, but it was not limited to one nerve, as formerly. The most sensitive point was, as before, on the upper lip, but in addition the

[1] Paper read before the Pittsburg Academy of Medicine, May 21, 1894.

slightest touch on the cutaneous surface above the eyebrow, in front of the ear, or over the horizontal ramus of the lower jaw, would bring on a paroxysm of pain pitiable to behold. On this account she was unable to wash that side of her face. Talking, eating, or drinking, even a gust of wind, was sufficient to throw her into an agony of pain. It was impossible at this time to examine the cutaneous sensibility of the affected side of the face. An effort to do so brought on such a paroxysm of pain that it was not repeated. It was learned from the patient, however, that the part previously rendered anesthetic by the removal of the superior maxillary nerve had partially regained its sensibility.

The futility of therapeutic resources, as previously demonstrated in this case, left nothing to be hoped for from medicinal treatment; nor did I feel justified in condemning her to a period of suffering in order to demonstrate again the correctness of this conclusion. The surgical aspect of the case was therefore the only one that received serious consideration.

As all three branches of the fifth nerve were now involved, it was obvious that any operation undertaken for the relief of this condition must be of such a nature as would destroy the conducting property of all three branches. It had been previously demonstrated in this case that removal of even a large part of the peripheral portion of a nerve did not permanently destroy its conducting property. After carefully weighing all the circumstances of the case I therefore decided to remove or destroy the Gasserian ganglion, in the hope that its destruction would cause degeneration of the nerve beyond the possibility of repair.

The patient was accordingly admitted to the Mercy Hospital, and on March 24th, with the assistance of my colleague, Dr. Buchanan, and the resident staff of the hospital, I performed the operation for removal of the Gasserian ganglion. Aside from the antiseptic details, the first step of the operation was to suture the margins of the right eyelids together, in order to avoid the danger of exposure of an insensitive eye. Experience has shown that this precaution is unnecessary, but I adopted it here because the right eye was the only good eye the patient had. Dr. Edsall, who examined her eyes, reported that there was almost complete blindness in the left eye from advanced optic atrophy, while the right eye also showed some evidence of beginning optic atrophy. It may be here added that the cause of this condition of the eyes was unknown, but it is probably due to a retro-bulbar neuritis.

The incision in the skin extended from a point directly posterior to the external angular process, backward to the posterior border of the lower jaw, downward to near its angle, and forward to the anterior border of the masseter muscle. The skin-flap thus outlined was dissected forward, care being taken to avoid the parotid gland and its duct, as well as the branches of the seventh nerve. The zygomatic arch was divided by passing a chain-saw round each extremity, through which holes had been previously drilled to facilitate wiring of the parts at the conclusion of the operation. The arch, with its attached masseter, was drawn downward, exposing the coronoid process of the lower jaw, which was also sawn through and displaced upward, with the attachment of the temporal muscle. The external pterygoid muscle was exposed by this dissection, and was detached from its origin on the pterygoid process of the sphenoid.

In this dissection the internal maxillary artery was wounded, with a resulting troublesome hemorrhage. After the bleeding was controlled a search was made for the inferior maxillary nerve. This was somewhat tedious, as the field of vision at the bottom of the now deep hole was constantly obscured by a free oozing of blood. Finally, the lingual branch was discovered and a fixation-ligature thrown around it for the purpose of using the nerve as a guide to the foramen ovale, which could now be felt by tracing the nerve upward.

A small trephine was in readiness to enlarge the opening of the foramen ovale, but its great depth and the obliquity of the base of the skull to the axis of the wound precluded the use of the instrument. I therefore used, instead, a narrow chisel, but unfortunately in guiding the chisel along my finger the latter slipped toward the median line until it was arrested at the foramen lacerum medium, which I at this moment supposed was the foramen ovale, and as a result of this error I drove the chisel not into the bony wall forming the outer border of the foramen ovale, but into the cavernous sinus. The withdrawal of the chisel was followed by an alarming hemorrhage, which immediately filled the cavity of the wound. The blood was arterial in character, but welled out instead of pulsating. The wound was rapidly packed. After a few minutes the packing was removed, but the blood welled out as furiously as ever. The cavity of the wound was again packed, sponges dipped in hot water being used. This was repeated four or five times. Finally the bleeding diminished, and in about half an hour was entirely arrested.

The foramen ovale could now be clearly defined, and was enlarged with the chisel until an opening about half an inch in diameter was made. Through this opening a small stout hook used by dentists was thrust about an inch in the direction of the root of the nerve. The hook was now used to lacerate the tissues, the object being to destroy or scrape away the ganglion. On withdrawing the hook something appeared in the opening, which I seized with forceps and drew outward. With it came the fixation-ligature and the lingual nerve. To my surprise the body proved to be the Gasserian ganglion, almost intact, a small portion of the root being attached. A considerable portion of the inferior maxillary nerve was attached, and the origin of the first and second branches could be detected. The manipulation of the hook within the skull was attended by a free but not troublesome hemorrhage. A drainage-tube was introduced to the bottom of the wound, which was closed, after replacement of the displaced tissues, in the ordinary manner.

The operation occupied two hours. On the fourth day the dressings were removed. The eye was found to be intact. The parotid gland had been wounded in the operation, and the salivary discharge was profuse for several days, until a communication was established with the cavity of the mouth. About a week after the operation the wound became infected, but ultimately the recovery was excellent. Since the operation there has been absolute freedom from pain. There is loss of sensation over the entire area supplied by the fifth nerve, but this loss is not absolute, certain cutaneous areas

retaining a slight degree of sensibility. The nutrition of the eye does not seem to be affected. The conjunctiva is almost completely anesthetic, with the exception of the inner third, which seems to be hyperesthetic. The right side of the tongue has lost its sensibility to touch and taste. The muscles of mastication are paralyzed, and the opposing muscles draw the teeth of the lower jaw out of line with the upper.

The method of operating for the removal of the Gasserian ganglion just described is similar to that devised by Rose, the pioneer in this operation. Horsley operated on one case by opening the cranium and exposing the nerve as it emerges from the pons. The patient died from shock in a few hours. Hartley, of New York, improved on this operation by opening the cranium without incising the dura, raising the temporo-sphenoidal lobe, exposing the ganglion and removing it as it lies beneath the dura mater. This method seems to have the advantage over the method of Rose, in the precision with which the ganglion can, under favorable circumstances, be removed, and in the absence of such disagreeable, and sometimes unavoidable, accidents as wounding of the parotid gland or the seventh nerve.

According to the appended table of the operations so far published, which is copied from an excellent report of an operation for removal of the Gasserian ganglion, by Dr. W. W. Keen and Dr. J. K. Mitchell, published in the *Transactions of the Philadelphia County Medical Society*, 1894, the operation has been performed forty-one times, including the present case, with the following results:

	Cases.	Recovered.	Died.	Mortality, p. ct.
Rose's method,	20	18	2	10.0
Hartley's method,	19	17	2	10.5
Horsley's method,	1	0	1	100.0
Method unknown,	1	0	1	100.0

WESTINGHOUSE BUILDING.

MEDICAL PROGRESS.

Craniectomy for Acute Mania following Traumatism.—PATTERSON (*Occidental Medical Times*, vol. viii, No. 6, p. 377) has reported the case of a man, twenty-eight years old, who a year previously had been kicked in the head by a horse, just in front of the right parietal eminence, and presented manifestations of acute mania. The scalp-wound healed promptly, but there had been constant headache from time of the accident. When not at work the man would rest his arms on a table and his head in his hands, at times remaining thus for hours without speaking. The pain was referred to the parietal and occipital regions of the right side. Pain was also felt in the left arm and leg, and there was numbness of the thumb and index finger of the left hand. A slight depression was found at the site of the previous injury. A portion of skull an inch and a half in diameter was removed from this situation without injury to the dura mater. The bone was abnormally thickened, and the membrane presented an unhealthy gray appearance. The scalp-wound was sutured, and healed without suppuration. For the first twenty-four hours after the operation the patient was perfectly sane. He then relapsed for a few days; but, after this, continuous improvement set in and progressed to complete recovery, although on over-exertion or on exposure to the hot sun there was complaint of pain in the head. The sensations referred to the left arm and leg entirely disappeared. The opening in the skull refilled with bone.

A Ptomaïn Obtained from the Urine of Influenza.—GRIFFITHS and LADELL (*Compt. rend. d. Séances de l'Acad. des Sciences*, t. cxvii, No. 22, p. 744; *Centralbl. f. Bakt., u. Parasitenk.*, B. xv, No. 25, p. 999) have succeeded in isolating from the urine of cases of influenza a ptomaïn having the formula $C_9H_9NO_4$, possessing toxic properties, inducing marked fever and causing death in animals within eight hours. It is obtained by alkalinizing a considerable quantity of urine with a small amount of sodium bicarbonate and adding half its volume of sulphuric ether. After filtration the solution is treated with tartaric acid, which forms with the ptomaïn soluble tartrates. The solution is finally again treated with half its volume of sulphuric ether. Upon evaporation the ptomaïn will be found. The body is a whitish substance, crystallizing in prismatic crystals soluble in water of slightly alkaline reaction. It forms a chlorhydrate, a chlorplatinate, and a chloraurate. It causes with phosphorwolframic acid a brownish, with phosphormolybdanic acid and with picric acid a yellowish, with tannic acid a reddish, and with mercuric chlorid, a whitish precipitate.

Gastric Ulcer unattended with Hematemesis.—WALKER (*Lancet*, No. 3691, p. 1301) has reported the case of a woman who had been suffering with pain in the epigastrium for some time, with occasional vomiting of food, but no hematemesis. From the character of the pain, from its limitation and from its persistency, ulcer of the stomach was diagnosticated. After many weeks of treatment with bismuth and pepsin and strict regulation of the diet, relief from pain was obtained, digestion went on easily, and it became possible to discontinue the medicine and relax the rigidity of the regimen. Some

time later, while under the care of another, the woman suffered from a serious illness, in which she suddenly, with a feeling described as that of impending dissolution, lost consciousness and became deathly pale. On the following day a considerable quantity of coagulated blood was passed by the bowel. Complete recovery followed a protracted convalescence.

A Ptomain in the Urine in a Case of Carcinoma of the Uterus.—At a recent meeting of the French Académie des Sciences GRIFFITHS (*La Presse Médicale*, June 23, 1894) described a ptomaïn that he had succeeded in extracting from the urine of a woman affected with carcinoma of the uterus. The body appears as a white substance, crystallizing in small needles, soluble in water, and of alkaline reaction. It forms a chlorplatinate, a chloraurate, and a chlorhydrate, and gives rise to a yellowish precipitate with phosphortungstic acid, a brownish precipitate with phosphormolybdic acid, and with mercuric chlorid, and a reddish precipitate with argentic nitrate. Analysis shows its formula to be $C_8H_5NO_3$. It possesses toxic properties, and is not found in the urine of healthy persons.

THERAPEUTIC NOTES.

Bone-Marrow in the Treatment of Pernicious Anemia.—FRASER (*British Medical Journal*, No. 1744, p. 1172) has reported a case of pernicious anemia in which remarkable therapeutic results were obtained from the administration of bone-marrow. The patient was a gardener, sixty years old, who presented vomiting, diarrhea, edema of the feet and ankles, moderate and irregular pyrexia, dimness of vision, retinal hemorrhages, anorexia, dyspnea, and complete prostration. For the first two weeks that the man was under observation no medicinal measures were employed. The hemocytes varied from 1,860,000 to 1,460,000 per cubic millimeter, and the hemoglobin from 28 per cent. to 30 per cent., the specific gravity being 1038. There was great distortion in the shape and variation in the size of the hemocytes, which did not form rouleaux. In the subsequent two weeks and a half, from six to twelve grains of ferrous chlorid were given daily. The hemocytes and hemoglobin steadily fell to 900,000 per cubic millimeter and 20 per cent., respectively, and the specific gravity to 1036. In a third period of eight days, from fifteen to twenty minims of arsenical solution were given daily, together with twelve grains of ferrous chlorid. Still further deterioration took place in hemocytes and hemoglobin, the former falling to 843,000, and the latter to 18 per cent.; the specific gravity remained at 1036. During a fourth period of three weeks the arsenic and the iron were continued in the doses named, but three ounces of uncooked ox bone-marrow were now given besides by the mouth. Almost immediate improvement ensued, so that at the end of this period the hemocytes numbered 1,800,000, the hemoglobin amounted to 35 per cent., and the specific gravity was 1042. The patient now began to recover strength and his appetite greatly improved. During a fifth period of twenty-six days the bone-marrow and the arsenic were continued, and salol was additionally given in doses of from fifteen to thirty grains daily. The improvement was maintained, the hemocytes rising to 2,470,000, the hemoglobin to 55 per cent., and the specific gravity to 1047. The patient had become stronger, his complexion had assumed a pinkish hue, and there had been gain in weight. During a sixth period of thirty-two days, bone-marrow and salol were continued and the improvement progressed. The hemocytes reached a maximum of 4,130,000, though they afterward fell to 3,400,000; the hemoglobin rose to 75 per cent., but fell to 70 per cent., and the specific gravity became 1058. The blood-cells formed rouleaux, and were more uniform in size and little distorted. The patient was able to do light work without fatigue; the functions of the alimentary system were well performed; edema, pains, headache, pyrexia, and venous bruits in the neck had disappeared, and the skin had assumed a healthy appearance. During a seventh period, extending over a month, bone-marrow and ferrous chlorid were continued. The hemocytes remained, with slight oscillations, at about 3,400,000; the hemoglobin averaged from 70 per cent. to 75 per cent., on one occasion reaching 80 per cent.; and the specific gravity remained steadily at 1059. All traces of retinal hemorrhage had disappeared. During the eighth period bone-marrow, iron, and salol were administered. The improvement was maintained, the hemocytes reaching 4,000,000, the hemoglobin 85 per cent., and the specific gravity 1060. The patient was now practically in a normal condition, with good appetite and healthy appearance.

Codein-Intoxication.—DUFF (*Columbus Medical Journal*, vol. xii, No. 12, p. 538), has reported the case of a woman who suffered from ovarian pain that was particularly severe at the menstrual periods, and for the relief of which it became necessary to give large doses of morphin. To avert the possibility of a drug-habit the use of codein was contemplated. Accordingly, half a grain was given by the mouth, and a few minutes later the same quantity hypodermatically. In a short time the whole body became greatly swollen, the face being intensely red, and appearing as if stung by bees. The skin was so hyperesthetic that the slightest touch on any part of the body caused the woman to cry out with pain. The lower extremities were cold and purple, the heart-sounds feeble and irregular, and the radial pulse almost imperceptible. By means of large doses of digitalis and whiskey, with hot applications, the failing circulation was soon restored, and in the course of five or six hours the woman felt as though nothing unusual had occurred. To establish the validity of the observation a small dose of codein was given on the following day, with the result of reproducing the symptoms in less degree.

A Convenient Mode of Administering Quinin.—For the ready administration of quinin to children, BOND (*Virginia Medical Monthly*, vol. xxi, No. 4, p. 343) recommends that the drug be made into pill-form with dilute acid, preferably aromatic sulphuric. The pills are crushed and mixed with a little brown sugar, placed upon the tongue dry, and washed down with a glass of water. Sweet chocolate may be used instead of sugar; or the pill may be preceded and followed by the use of liquorice-root. The same principle of procedure may, of course, be employed with other drugs to be administered to children.

PURIFICATION OF WATER.

ALL large cities are brought ultimately to the serious consideration of methods of treating water-supplies so as to secure the removal of dangerous materials. The reckless way in which the communities of the Atlantic slope have squandered the bounties of Nature, destroying forests, wasting mineral resources, and extending cities and manufacturing-sites without any care as to the pollution of water-courses has at last brought its harvest, and now some inquiry is made as to how the pound of cure may be obtained.

The City of Philadelphia is a striking example of neglect in the matter of water-supply. Attention has been called for years to the necessity of engineering-devices for securing storage and purification, but the evil influence of jobbery has aided the tendency to *laisser faire*, and the stress is increasing each year. It is, however, not an unmixed evil that Philadelphia has done nothing in the way of bettering its supply of water until the present, for it is now possible to speak positively of plans of purification and to undertake those which are demonstrably satisfactory.

It has been clearly recognized for some years that the conveyance of disease by water is due mainly to living organisms, and it is also known that these organisms have a comparatively brief life, and may be removed by several means. The mere subsidence of fine particles, sand, mud, etc., will carry down a very large proportion of the microbes, and by the use of a coagulant such as alum, a further purification will be attained. In fact, as far as surface-waters are concerned, it is generally found that when quite clear they are but little contaminated.

Experiments on filtration have been carried on for many years, but it was not until accurate bacteriologic determinations became possible that the inferences from experiments could be relied upon. The earlier observations recorded merely such separation of suspended matter as might be detected by the naked eye or indicated by analysis; but the essentially dangerous ingredients in water mostly elude both of these methods.

Culture of microbes in solid media affords the means of studying the effects of storage and filtration. It is admitted by most competent authorities that mere microbe-counting is far from constituting a reliable means of determining the safety of a water. To take a little water from a river or lake, mix it with sterile nutritive gelatin, place it in an incubator for some days, and then count the visible colonies will give a result of no value. If, however, repeated and duplicated cultures are made under constant conditions, with samples before and after specific treatment, storage, filtration, precipitation, etc., results are obtained which, even if affected (as they generally are) by a large constant error, are closely comparative. This is the work that has been done for the last few years and is still going on in several parts of the world.

Outside of the practical operation of filtering-systems in many cities, the work of the Massachusetts State Board of Health is most valuable. This work was carried on for several years in the laboratory upon so large a scale that the Board felt justified in establishing it in practice, and under its auspices several towns have been supplied with systems of sewage-disposal based on simple sand-filtration so efficacious that the effluent water is fit to be thrown at once into streams which serve for the supply to towns below. It must be noted that these efficient methods have been applied to actual sewage, not merely to polluted waters, and that the results are not vague or incoherent, but have been studied in many aspects. The effects of temperature, rate of operation, size and nature of the particles compos-

ing the filter, and the bacteriology and chemistry of the applied and effluent water have been noted in great detail. The process is one of sand-filtration. It has been demonstrated that sewage can be purified at the rate of two million gallons per acre per day.

The action of the sand-filter is not merely that of a strainer; biologic changes take place in it by which microbes are killed and the food necessary for their vitality destroyed.

Cities suffering from pollution of their water-supply may certainly take heart from the results just noted. Philadelphia, for instance, has an abundance of water within its own boundaries, but neither the Schuylkill nor the Delaware is of constantly satisfactory purity. With the proper filters and storage-reservoirs both these streams could be utilized, and the figures cited would show that a filter area of fifty acres would purify the water under the worst conditions at the rate of more than one-hundred million gallons in twenty-four hours.

It is further to be noted that in the course of the studies made by the Massachusetts Board it has been found that the storage of purified water can be safely carried out. Such water does not become objectionable in taste or odor. The comparatively extended storage-facilities that Philadelphia now possesses will be available for holding the filtered water, and filters may be treated at convenient points without reference to levels, as it is easy to pump into the distributing-reservoirs.

This is not the place to enter upon estimates of cost or suggestions of construction, but a single calculation will perhaps be of interest. The number of deaths annually from typhoid fever in Philadelphia is, in round numbers, six hundred. This means certainly six thousand cases, and we will not be in error in assuming an average loss of one hundred dollars for each case. This would make a total cost of six hundred thousand dollars per annum. It would be rash, perhaps, to claim that filtered water would prevent all these cases, but the experience of London, Munich, and Berlin would justify the assumption that four-fifths of the cases would be prevented. This would give a net saving of nearly five hundred thousand dollars, which would doubtless far more than exceed the interest-charge upon the constructions required. Outside of this "business" view, it must be remembered that typhoid fever largely affects adults at the period of greatest usefulness and when family ties are most precious and endearing. Filtration and storage of the waters at its gates are the methods of securing to Philadelphia a pure water.

EDITORIAL COMMENTS.

The Transmission of Tuberculosis from Mother to Fetus.— Since the demonstration of the bacillary origin and the etiologic unity of tuberculous processes, former views as to the hereditary transmission of the disease have undergone rather radical change. It has been assumed that what was transmitted from the tuberculous parent to its subsequently infected offspring was a peculiar, indeterminate depravity of tissue that facilitated the lodgment and multiplication of the effective causative factor, the tubercle-bacillus. Nevertheless, the possibility of direct transmission, in some cases, from mother to fetus, as occurs in the case of other infectious diseases, such as scarlatina, smallpox, yellow fever, and the like, could not be excluded. The explanation of cases of this category, and the determination of the mode of transmission, were for a time matters of no little difficulty. A sufficient number of observations, both in lower animals and in man, have now accumulated to show that the fetus may become infected by the mother through the medium of the placenta. Thus, BIRCH-HIRSCHFELD and SCHMORL (*Ziegler's Beiträge*, B. ix, S. 429; see the NEWS, July 11, 1891, p. 48) found in one case tubercle-bacilli in the placenta, in the intervillous spaces, in and between the epithelia of the villi, in the lumen of divided chorial vessels, and in capillary vessels of the fetal liver, and three guinea-pigs inoculated with pieces of fetal tissue became tuberculous. Characteristic lesions could not be discovered in the fetus, although several nodules were found in the placenta. Two additional contributions of a most suggestive nature have been made to this subject by LEHMANN. The first case (*Deutsche medicinische Wochenschrift*, 1893, No. 9, p. 200) was one of miliary tuberculosis occurring in a woman with a strong family history of tuberculosis and in the eighth month of pregnancy. The first physical evidence of the disease showed itself as a tubercle of the choroid. After death, involvement of lungs, pleura, kidneys, liver, spleen, the cerebral meninges, and choroid, was found, while in the pons and right cerebral peduncle there was an area of recent softening; the peritoneum and intestines were uninvolved. In the placenta, in three or four situations, were found circumscribed, round, gray nodules, as large as millet-seeds, both upon the uterine surface, and somewhat more deeply. Upon histologic and bacterioscopic examination these nodules proved to be classic tubercles, containing giant-cells and tubercle-bacilli. The fetus, which was dead, presented no characteristic lesions. The second case (*Berliner klinische Wochenschrift*, 1894, No. 26, p. 601) occurred in a woman suffering with chronic pulmonary and laryngeal tuberculosis. The child died ten days after birth, but no tuberculous lesions were demonstrable. Careful examination of the placenta, however, disclosed, both in its fetal as well as its maternal portions, the presence of tubercles having a characteristic histologic structure and containing tubercle-bacilli. These observations are of extreme interest and of great importance. They suggest, at least,

one mode of transmission of tuberculous disease, which may be more common than observation has hitherto shown it to be, for, unless carefully looked for, the placental lesions may readily be overlooked. The demonstration would become conclusive with the exhibition of fetal lesions.

The Unauthorized Renewal of Prescriptions.—In a communication that appears in a recent number of the *American Journal of Pharmacy* a graduate in pharmacy takes the ground that it is optional with the druggist whether or not he shall renew a prescription, even though this be accompanied by a request from the prescriber that it be not renewed without special authorization. He quotes pharmaceutic authority that such a request ("command" it is designated) on the part of the prescriber is "both useless and presumptuous." Useless it may be with a certain class of druggists, but certainly not presumptuous, for surely the druggist would not undertake to instruct the physician in the arrangement of the contents of his prescription, and the character of the directions is not less important than the quantities of the constituents. It is admitted that there is some danger in the renewal of certain prescriptions, such as those that contain poisons and drugs the use of which is likely to lead to the formation of habits, and that there is possibility of abuse with regard to others, such as are intended for common ailments, and may be transferred from one person to another, but the privilege of renewal, it is maintained, resides with the druggist, although this particular writer avers that he individually has always respected the physician's request. To do otherwise would be nothing less than a breach of confidence. Even the renewal of prescriptions in the absence of specific instructions is for the druggist to usurp the position of the physician in the treatment of the case, and to assume that the former is as cognizant of the therapeutic indications as the latter. We do not care here to enter upon a discussion of the hackneyed question of the ownership of the prescription, but if any druggist proved so faithless as to ignore our printed, written, or verbal request as to the renewal of prescriptions, we should feel called upon to warn our patients against dealing with so dishonorable and untrustworthy a person. Counter-prescribing, nostrum-dispensing, and indiscriminate renewal of prescriptions are evils of which the pharmaceutic profession were well rid, but the failure to observe the explicit instructions of the prescriber would be a breach of faith that could not be condoned and would not be tolerated. With equal right the druggist might in his judgment change the proportions, or the quantities of the ingredients, or even the ingredients themselves. We can can scarcely believe, however, that there is any considerable number of pharmacists who would prove themselves so unworthy of confidence as to fail in the matter of prescriptions to comply with any legitimate request on the part of the physician, and surely the desire to control the treatment of a patient for whose welfare he assumes the responsibility cannot be considered as otherwise than legitimate.

The Proprietary-medicine Evil.—In an article in a recent number of the *Bulletin of Pharmacy* a contributor from Pennsylvania offers certain suggestions looking to the correction of what is known in the drug trade as "cutting"—that is, the selling of nostrums and other articles of their class below established prices. The first proposition is to so amend the trade-mark laws as to abolish the right of proprietorship in medicine or medicinal preparations. The second proposition recommends the enactment of a law making it an offense punishable by fine or imprisonment, or both, for any person to sell or offer for sale any so-called patent or proprietary remedy the sworn formula of which is not registered with the Secretary of the State Pharmaceutical Examining Board, and which shall be open to inspection, unless such preparations, under certain restrictions, are prepared by a citizen registered under the State pharmacy law. It is further provided for that the manufacture or sale of proprietary or so-called patent medicines be allowed if the same be shipped outside of the Commonwealth. We can cordially indorse the first proposition and the first part of the second. The former would make the other measures unnecessary, except in so far as applies to preparations of foreign manufacture. We fail, however, to see the equity and the virtue of the condition that would permit the manufacture or sale of nostrums, providing they are disposed outside of the Commonwealth. The only way to eradicate the nostrum-evil, and with it the "cut-rate" evil, is to absolutely forbid the manufacture and sale of preparations whose constitution is kept secret and is not controllable by proper authority. The disease is a serious one; palliative measures will not suffice; the required remedy must be a radical one.

REVIEWS.

The Theory and Practice of Medicine. Prepared for Students and Practitioners. By James T. Whittaker, M.D., LL.D. New York: William Wood & Co., 1893.

The author of this book states in his preface that the most work has been put upon the infectious diseases. We had been prepared for this by the previous writings of Dr. Whittaker, as well as by the dedication of the present book to Drs. Robert Koch and George M. Sternberg. In looking over its pages we are disposed at first to question the advisability of devoting almost the half to infectious diseases, but as the author includes many affections commonly described with the diseases of special organs, the departure from the customary distribution of pages is not in reality as great as would at first seem. This attempt to include all infectious processes in one part, whether affecting individual organs or the general system is, perhaps, most scientific, but has many practical disadvantages.

It is true that croupous pneumonia seems to be an infectious disease, but in its clinical relations and in its treatment it stands so near to broncho-pneumonia that we are inclined to question the advisability of separating the two. The zeal to fully round the subject of the infections has led the author to include hay-fever, which, according to his own description, is not an infection at all. Syphilis is wisely included; but gonorrhea seems to us more properly a surgical disease.

The chapters on the diseases of the digestive system are clear and practical. The discussion of functional and

neurotic disorders of the stomach might have been more extensive, however. We turn with some interest to the treatment of appendiceal and cecal inflammations, but find the author far more conservative than the majority even of our medical teachers, not to mention surgeons.

The following statement may be fairly questioned: "Purgation which secures osmosis is beneficial in salpingitis, but injurious in typhlitis. Where the bowel is itself inflamed, purgation is bad practice." Doubtless there are cases in which salines may not be used; as surely, however, there are others in which this treatment far outranks opium in efficiency.

Among the pulmonary diseases capillary bronchitis and catarrhal pneumonia are separately described. This is rather retrograde teaching. Modern pathology tends to the identification of these conditions.

The subsequent chapters, on Circulatory Diseases, Diseases of the Blood, of the Urinary Organs, and of the Nervous System, are all clearly written and interesting.

On the whole, this book is a satisfactory expression, of moderate size, of the medicine of to-day; but in places, we fear students will find difficulties that will lead to misunderstanding. It seems scarcely advisable to call pseudo-leukemia "a subvariety of leukemia" in a text-book, though some writers have made this claim in controversial papers. We cannot subscribe to the following too minute division of the hemorrhagic diathesis: "The hemorrhagic diathesis is sometimes inherited, but is usually acquired. When inherited, it must be distinguished from hemophilia, which is transmitted only in certain directions." The statement that locomotor ataxia "may follow any acute infectious fever, especially diphtheria," may be true, but the pseudo-ataxia of post-diphtheric palsy should have been alluded to in this connection, and doubtless this is generally mistaken for ataxia. In several other places we notice similarly lax expressions, and call attention to them because, though they may be accurate, they will probably confuse students of medicine, and to this extent mar an otherwise commendable work.

Syphilis in the Innocent (Syphilis Insontium) Clinically and Historically Considered, with a Plan for the Legal Control of the Disease. By L. Duncan Bulkley, A.M., M.D., Physician to the New York Skin and Cancer Hospital, etc. Pp. 398. New York: Bailey & Fairchild, 1894.

The subject is an important one viewed from every light, and has been handled by the author in a masterly and practical manner. It is shown very conclusively, in the first place, that syphilis is not necessarily a venereal disease, but may be acquired innocently, in numerous ways, by any man, woman, and child. This is not only pointed out, but is illustrated by many clinical cases. The non-venereal aspect of the disease, and the numerous modes by which the virus may be conveyed from one individual to another, contribute the theme with which the greater part of the volume is taken up. A unique classification of the modes of infection is given, which includes over one hundred methods of transmission, grouped under three main heads: 1. In connection with household and industrial life. 2. In the case of children. 3. In professional pursuits.

One of the most interesting and valuable portions of the book is the very complete and carefully compiled chapter giving a synopsis of facts arranged in accordance with the classification of modes of infection. Thus, here are collected and classified all the cases that have been reported in which the disease was conveyed by such ways as lactation, accouchement, circumcision, vaccination, and eating and drinking from the same utensils. Infection from tobacco-pipes, surgical instruments, wearing-apparel, and many other articles is referred to. Infection by contact of finger is also illustrated by cases.

The subject of syphilis in the infant is one of the most carefully elaborated and suggestive in the book, and is worthy of attentive consideration. The modes by which the virus may be conveyed to the child are incredibly numerous, and are supported by the observations of many well-known syphilographers.

By far the most original and important chapter concerns the legal control of the disease. The author justly contends that the public health demands that individuals should be protected against this malady, which affects the innocent and guilty alike. The disease should be placed under the control of Boards of Health. It should be under legal restrictions quite as much as other contagious diseases.

Tarnowsky, a Russian authority, gives the case of one syphilitic woman who contaminated no less than three hundred men within a period of ten months. It should be regarded as a criminal offence to transmit the disease wittingly, as much so as to communicate smallpox or scarlatina. The medico-legal aspect of this question, and practical suggestions for the control of this disease, are entered into by the author, and will repay study.

An alphabetic bibliography, embracing nearly one hundred and fifty pages, and very complete, is in itself a valuable contribution to the subject. The book is replete with interesting facts bearing on the question, from whatever point the matter is viewed, and it is plainly shown that considerable syphilis is communicated in innumerable ways to the innocent.

A Hand-book of Medical Microscopy for Students and General Practitioners: Including Chapters on Bacteriology, Neoplasms, and Urinary Examinations. By James E. Reeves, M.D. With a Glossary and numerous Illustrations (partly in colors). Philadelphia: P. Blakiston, Son & Co., 1894.

If enthusiasm is communicable (that it is, there can be little doubt), no one who reads Dr. Reeves' book will fail to become imbued with a most zealous desire to use the microscope whenever possible. In glowing language the author speaks of the inestimable value of the microscope to medical science, and cites a number of interesting illustrative examples. A practical experience extending over many years (Dr. Reeves is one of the pioneers in medical microscopy in this country) enables him to speak authoritatively on methods of technique. In this little manual he has greatly simplified these, and with the book before him, anyone possessing the necessary outfit can prepare sections without much difficulty. The author's preference is for paraffin as an imbedding medium. Excellent results are no doubt obtained with it. The preparations of Dr. Reeves, some of which

it has been our pleasure to see, demonstrate this clearly enough; nevertheless, we incline to the belief that celloidin is superior. The author has devised a double stain of hematoxylin and sodium sulphindigotate, which has given him excellent results. He has also elaborated a new stain for fibrin, in which safranin is employed.

The chapter on bacteriology is concise, yet comprehensive. The special method of staining the bacillus typhosus in sections will be welcomed by bacteriologists. In the section on tumors the author adopts a classification which is similar to that of Thoma. The examination of urinary sediments is treated judiciously in a chapter of nearly forty pages. In this branch of microscopy illustrations are of special value, and it is a satisfaction to note that they have been supplied with great liberality. The chapter on the blood is good, but could be made more complete by the addition of a section on the methods of staining the corpuscles.

The book distinctly fills a place in our medical literature. Its convenient size, and the abundance of valuable suggestions contained in it, will, in our opinion, make it popular with those for whose use it is designed—students and general practitioners.

The Treatment of Typhoid Fever. By D. D. Stewart, M.D., Lecturer on Clinical Medicine in the Jefferson Medical College, etc. The Physician's Leisure Library, 8vo., pp. 104. Detroit: George S. Davis, 1893.

Within the limits of this brochure Dr. Stewart has given a faithful presentation of the modern treatment of that widespread affection, typhoid fever. With a few words as to the etiology, the prophylactic measures to be adopted are first succinctly pointed out. Then the general management of the case is fully considered, and, rightly, the first place is given to cold bathing according to the method of Brand, which is lauded in the highest terms, in entire accord with the views of those who have had the largest experience with this method of treatment. So-called expectant and expectant-symptomatic treatment is condemned, while a strong indorsement is given to the antiseptic treatment of the disease. Brief reference is also made to the biologic treatment—*i. e.*, the use of products of the typhoid and of other bacteria. The concluding section of the book is devoted to a consideration of special symptoms and complications. The book is admirably written and cannot fail to be of service. Upon one point, however, we must express our difference, and that is the sanction under any conditions of the use of the coal-tar antipyretics in the course of typhoid fever. The very language used on pages 78 and 79 in their recommendation is an argument against their use: "Where the cold bath is inadmissible and the pack or cold sponging alone is insufficient to keep the axillary temperature within 103° F. in a patient in whom the coincident presence of mild cerebral or cardiac symptoms indicates mischief likely to result from the toxemia producing the pyrexia, moderate doses of one of the internal antipyretics, such as acetanilid, antipyrin, phenacetin, or quinin, may be cautiously resorted to." Surely one would not wish to add to an already existing toxemia the baneful effects likely to result from the administration of such drugs as antipyrin and its congeners, and which, besides, as is elsewhere in the brochure stated, tend to interfere with the elimination in the urine of the toxic products generated in the natural course of the disease.

Essentials of Nervous Diseases and Insanity; Their Symptoms and Treatment: A Manual for Students and Practitioners. By John Shaw, M.D., Clinical Professor of Diseases of the Mind and Nervous System, Long Island College Hospital Medical School, etc. Second edition, revised. Forty-eight original illustrations, mostly selected from the author's private practice. Philadelphia: W. B. Saunders, 1894.

The fact that a second edition of this little work is called for within two years would seem to show that it has been regarded with some favor. Certainly it has merits as well as defects, some of which are almost inseparable from a work of this size. Very few changes have been made in the present edition, which contains exactly the same number of pages as the first edition, viz., 190. As the author has seen fit to append a bibliography after the description of each disease, it seems to the reviewer that reference to some of those papers which have been published within the last two years should have been made. We miss a description of myxedema, and do not find any reference to thyroidectomy as a means of treatment in Basedow's disease. The defects of the work are of omission rather than commission, and on the whole it is of unusual merit. Some of the descriptions of diseases are quite good. The student or physician somewhat familiar with one of the larger treatises on nervous diseases will, upon perusal of this compend, be able to refresh his memory on many points in a short time. Some of the illustrations are cleverly executed, especially figures 45 and 46, representing two types of melancholia. The publisher's work is well executed.

New Truths in Ophthalmology: As Developed by G. C. Savage, M.D., Professor of Ophthalmology in the Medical Departments of the University of Nashville and Vanderbilt University. Thirty-two illustrations. 8vo, pp. 152. Published by the Author, Nashville, Tenn., 1893.

This brochure discusses the obscurities that surround the physiology of extra-ocular muscle-equilibrium, and records a search into the uncertainties of the etiologic factors at work in the disturbance of such equilibrium.

The author has devoted considerable time to this rather complicated and not well-understood condition, and has given much study to its practical correction.

Dividing his subject-matter into three parts, in part first, he gives us his views and beliefs upon the harmonious and symmetric action of the oblique muscles, and shows why these muscles are made to rotate in cases of oblique astigmatism.

There are also studies in rhythmic contraction and relaxation for the purpose of developing the ocular muscles; thoughts in reference to the laws of projection; some clinical data upon heterophoria, operative procedures, etc.

The discomforting impression gained from the title-page and the preface does not invite detailed criticism, a task, moreover, that must be left to the specialists and the journals of ophthalmology.

DE LA MALADIE DE BASEDOW ET EN PARTICULIER DE LA PATHOGÉNIE. Par FREDERICK CHAMBERLAIN, Docteur en Médecine du Yale Medical School; Docteur en Médecine de la Faculté de Paris. 8vo. pp. 143. Paris: Henri Jouve, 1894.

THIS admirable monograph is a comprehensive *résumé* of our present knowledge of the subject of exophthalmic goiter. It contributes nothing original, but discusses fully modern notions of the pathogenesis of the disease (and these deal largely with the functions and derangements of the thyroid gland), although no opinion is expressed as to the preferable theory. Treatment is concisely considered, and an extensive bibliography is given.

THERAPEUTICS OF CHOLERA (Cholera Asiatica). By P. C. MAJUMDAR, M.D., Graduate of Medical College, Calcutta, India; Corresponding Member of the American Institute of Homeopathy, and Honorary Member of the International Hahnemannian Association, etc. Philadelphia: Boericke & Tafel, 1893.

VEHEMENT denunciation of the "Old School," with genuine Hahnemannian disdain for etiology and pathology, and extravagant claims for "New-school" therapeutics, contradicted, however, by the bewildering variety of remedies and indications later given, are the principal features of this book.

CHART OF THE OFFICIAL CHEMICAL SALTS, BOTH INORGANIC AND ORGANIC, OF THE U. S. P., 1890. Showing the Methods of Production, together with a Schedule of Neutral Principles and Phenols. By JAS. KENNEDY, Ph.G., M.D., Professor of Pharmacy and Dean of the Faculty of the Department of Pharmacy of the University of Texas.

THE title of this chart explains its uses and purposes. The table is taken from a treatise on the *Theory and Practice of Pharmacy and Pharmaceutical Chemistry*, by Profs. Kennedy and Morris.

SOCIETY PROCEEDINGS.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Eleventh Annual Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

FIRST DAY—MAY 29TH.

THE PRESIDENT, DR. ANDREW H. SMITH, of New York City, made some introductory remarks, and afterward read a paper entitled "Alimentation in Pulmonary Disease." He pointed out that while feeding is important in all diseases, it seems to be especially important in lung-cases. Food may have a good or a bad effect, as it is assimilated or not. The exact mode of blood-production is not yet known, nor yet where the corpuscles are formed. For perfect assimilation of food there must be oxygenation by means of the oxygen furnished by fresh air. Unassimilated food is a direct source of irritation to the economy. For full and perfect metabolism the blood must be fully aërated. An intelligent study of pulmonary tuberculosis clearly shows the folly of overfeeding, by embarrassing the diseased lungs. As little food should be given as may be necessary.

In pneumonia the treatment has consisted in forcing food on the stomach. Such efforts to maintain the patient's strength were a mistake. Harm results from crowding the bloodvessels. Double work is thrown on the heart when such a course is adopted in pneumonia and other pulmonary diseases.

What then shall the diet be in pulmonary disease? All forms of food originally were derived from the vegetable kingdom. The flesh of animals is more readily digested than carbohydrates. Nourishment should be given in small quantities and repeated frequently, but there should be no forcing of food on an unwilling stomach. Water should be given freely. The instinctive feeling of the patient may be relied on as to what will keep the blood fluid.

In chronic pulmonary disease high nutrition is necessary, as in fibroid lung. In such cases the patients are almost bloodless. The pabulum from the food does not get into the circulation. Under these conditions hemoptysis occurs sooner or later. Respiration is interfered with and oxygen cannot enter the blood, and hematosis and the whole process of metabolism suffer. In treating such chronic cases animal food cannot be solely relied on. Digestion is often deranged, and a life in the open air is of immense value.

Dr. Smith reported good results from rectal injections of defibrinated blood, of which two ounces were injected at a time. As a rule no traces of blood were found in the stools after such injections.

Alcohol is believed to have a nutritive value in acute and chronic cases of pulmonary disease. When the odor of alcohol is found in the patient's breath he is getting too much.

DR. BOARDMAN REED, of Atlantic City, read a paper entitled "The Relation which Alimentation should bear to Oxygenation in Lung-diseases." He dwelt at length on the subject of forced feeding. He considered an excess of food as absolutely injurious. There should be a ratio between the oxygen inspired and the food ingested. When the in-take of oxygen is large, a large quantity of food can be assimilated. A patient with impaired lungs requires less food. Overfeeding simply results in injury, as the patient cannot assimilate the excess of food.

When fever is present in lung-cases rest of body is necessary, and this may be secured in-doors or out of doors. An abundance of fresh air is always essential.

Climate *per se* was not considered of so much importance in cases of pulmonary disease. The colder the air the better, if the patient can breathe it freely. Change of climate benefits many, stimulating nutrition.

DR. ANDREW H. SMITH, in reply to a question, said that it was his rule to have his hospital-patients lightly fed for a few days, as all acute febrile diseases are attended with a suppression of the digestive fluids. In a short time the body becomes accustomed to an abnormally high temperature and to the products of bacterial activity.

DR. ROBERT H. BABCOCK, of Chicago, said that there were two points of great importance—staying the waste of the tissues that takes place in pulmonary disease, and building up the body. The taking of fat lessens the demand for air. In lung-disease there is a diminished ability to absorb oxygen. Air, when fresh and cool, acts

as an antipyretic, and improves the assimilative powers of the patient.

Dr. Van Ruck, of Asheville, N. C., stated that he had noted marked improvement in cases in which defibrinated blood had been injected per rectum.

Dr. D. W. Prentice, of Syracuse, N. Y., said that the amount of carbonaceous food had to be watched. He cited the case of an asthmatic who could induce an attack at will by using a full mixed diet, and could promptly check an attack by regulating the diet and restricting it to lean meat and vegetables.

Dr. Albert L. Gihon, U. S. N., mentioned the case of a tuberculous marine who seemingly got well by working in the open air, gardening—the tubercle-bacilli disappeared from the sputum.

Dr. Glentworth R. Butler, of Brooklyn, N. Y., read a paper entitled "The Method and Value of Supervised Exercises and Diet in the Prophylaxis of Pulmonary Disease." He defined pulmonary tuberculosis as a disease of malnutrition, of microbic origin, to which certain persons are predisposed by undue vulnerability of the tissues. The remedy is comprised in climate, abode, personal hygiene, exercise and its corollary, rest, diet, etc. The patient must be given explicit directions as to how to live.

Dr. Otis, of Boston, warmly approved Dr. Butler's system. To-day, he said, modern gymnastics were applied scientifically. He quoted from his very large experience in Boston. All the exercises there were conducted by an expert. He saw fully five hundred young men yearly who underwent gymnastic training. Improvement resulted in all the cases.

Dr. John Winters Brannan, of New York City, expressed himself as strongly in favor of deep breathing and pulmonary gymnastics.

A paper entitled "The Importance of Mouth-cleanliness in the Prevention of Disease," by Dr. Clarence C. Rice, of New York City, was, in the absence of the author, read by title.

Second Day—May 30th.

A paper entitled "A Plea for the Earlier Recognition of Pulmonary Tuberculosis, and the Adoption of Proper Climatic Treatment," by Dr. H. B. Moore, of Colorado Springs, was, owing to the absence of the author, read by title.

Dr. Vincent Y. Bowditch, of Boston, read a paper entitled "Three Years' Experience in the Sanitarium Treatment of Pulmonary Disease near Boston." The observations were made at the Sharon Sanitarium near Boston, an institution intended for working-women, the majority of patients being shop-girls.

An abundance of sunlight and pure air are provided for; every room is freely ventilated. Broad piazzas surround the building, and the patients are kept out in the coldest of weather. No carpets or rugs to entangle dust are used. The cleaning is done by passing damp cloths over the wood-work and modern sanitary precautions are taken.

Of 48 cases, 8 had bronchitis and the remaining 40 various forms of pulmonary tuberculosis; 10 had been discharged with the disease arrested. No case was said to be cured. Most of the 10 had been away for from eighteen to twenty-four months and reports from them were regularly received. Of 8 arrested cases 7 showed excellent results. In only 3 of these were bacilli to be found. In many cases the bacilli were not found, although the patients presented other evidences of pulmonary tuberculosis, such as cough, hemorrhage, expectoration, malaise, and night-sweats.

One patient that had been under care for two years had gained 28 pounds in weight. Another that had cough and hemorrhage had gained 14½ pounds in weight in four months.

Bacilli had been found in six cases classed as improved.

Dr. Roland G. Curtin, of Philadelphia, spoke of observations made in the Philadelphia Hospital in the wards for tuberculous patients. In 1888–1889 the sputum of these patients contained tubercle-bacilli. In 1890, influenza appeared with the result that one-half of the old cases died. In 1891, of 28 cases, the sputum of 15 contained no tubercle-bacilli. In a number of post-mortems made, most careful examination of the tissues failed to disclose the presence of tubercle-bacilli.

Dr. Roland G. Curtin, of Philadelphia, read a paper entitled "Creosote, Guaiacol, and Benzoyl of Guaiacol in Phthisis." He gave a *résumé* of his experience with the several agents named, as well as the subcutaneous injection of phenic acid. The latter was very painful. Beechwood creosote and guaiacol have chemically much in common. Some patients can take large and others but small doses of creosote. Those that bear it best, as far as the stomach is concerned, show increase in weight. In acute pulmonary tuberculosis, with high temperature, no benefit was observed to result from guaiacol. The class most benefited is that whose members present slight fever and poor digestion. Dyspepsia may be cured by phenic acid. Guaiacol is used in pill-form. Guaiacol benzoyl was found to act much the same as guaiacol, and certainly no better.

Dr. A. L. Loomis does not believe that the agents named exert any special action. In many cases patients seem to do just as well without drugs. In a certain class these improved digestion.

Dr. Van Ruck, of Asheville, S. C., said that four years ago he had used creosote hypodermatically. The injections caused much pain, but had no appreciable effect on the tubercle-bacilli. Creosote is beneficial in bronchial and gastro-intestinal cases.

Dr. W. M. Gibson, of Utica, N. Y., had found that creosote had an effect on the blood, moderate doses inducing an increase of the colorless corpuscles after a meal, thus favoring a better phagocytosis.

Dr. Elsner, of Syracuse, N. Y., said that in both hospital and private practice he had obtained good results with creosote. He dwelt on the difficulty in making an early diagnosis in tuberculosis, and pointed out that the sputum does not become tuberculous until there is a cheesy infiltration of the lungs. There must be breaking down of pulmonary structure for tubercle-bacilli to find their way into the sputum.

Dr. A. L. Loomis said that he had found tubercle-bacilli in the sputum in the absence of destruction of tissue. He referred to the case of a young man, who two years ago had quite a profuse hemorrhage while undergoing examination. Specimens of the blood and expectoration were examined, and a large number of

bacilli found, although careful physical examination failed to disclose evidences of pulmonary disease. The hemorrhage was repeated for three or four days. The man now seems well. Bacilli may lodge in the bronchi without entering the lung-tissue, while they may gain entrance into the lungs through the lymphatics and the bloodvessels.

Dr. Elsner thought that in the case cited by Dr. Loomis there might have been previous tuberculous infiltration and necrosis in the ruptured vessel.

Dr. Glasgow, of St. Louis, deemed creosote most valuable. He dissolved the creosote in a little whiskey, and had the solution mixed with cream and milk. He got excellent results.

Dr. Frederick I. Knight, of Boston, read a paper entitled "Shall Anything be Done by Legal Authority to Prevent the Spread of Tuberculosis." He pointed out that although twelve years have passed since the real nature of tuberculosis had been made public, but little seems to have been done to prevent its spread.

A paper entitled "Further Reports of Cases of Phthisis Treated at Colorado Springs," by Dr. S. E. Solly, of Colorado Springs, was in the absence of the author read by title.

Dr. Knight offered the following preamble and resolution:

"*Whereas*, The American Climatological Association was founded, among other objects, to promote the study of the nature and treatment of diseases of the respiratory organs; and

"*Whereas*, Tuberculosis is the most fatal of such diseases; and

"*Whereas*, Modern research has placed this disease among the infectious, and hence, to some extent at least, among preventable diseases;

"*Resolved*, That this Association strongly recommends all Boards of Health of this country to adopt measures tending to the restriction of the disease."

Third Day—May 31st.

Dr. Leonard Weber, of New York, read a paper entitled "The Condition of the Heart in Diabetes, and its Relation to Diabetic Coma." He reported sixty cases of diabetes mellitus; the majority were over forty five years old, and the larger number were in women. Two cases had occurred in children; one in a child aged twelve, following scarlatina; death ensued three months after the appearance of the disease; in the second child the symptoms followed the excessive use of potassium bromid; recovery ensued.

Of forty cases in advanced life there was none of recovery. The duration of the disease was from three to twenty years. In a number of cases it averaged ten years.

The causes of death were varied. In some fatal pulmonary complications developed; in others, disease of the kidney. Half the cases died in sub-acute coma. In these the heart was overworked and exhausted. Such cases often presented arterial sclerosis, and in them the odor of acetone in the breath was very marked.

Syncope appeared first, and was speedily followed by cardiac failure. Heart-disease is not so rare in these cases.

Neuro-muscular disease may follow diabetes—*e. g.*, fatty degeneration of the heart, etc. Doubtless the poisonous action of the ptomaïns has an influence. Some cases present gastro-intestinal symptoms. Again, the disease may be associated with chronic interstitial nephritis. The diet in such cases requires careful study.

The disease is protean in its manifestations, and every case should be made a special study. It is often associated with disease of the heart and brain and with posterior spinal sclerosis. The therapeutic indication is to reduce the glycosuria as much as possible.

Dr. Weber employs rest and massage. He attempts to get rid of the sugar by the usual alkaline treatment. If soda-solutions do not agree, he gives opium in some cases, and watches its effect on the heart and stomach. He thinks well of the method of Schott.

In cases of diabetic coma it is most important to evacuate the bowels and fill the lower colon with an alkaline solution.

Dr. Robert H. Babcock, of Chicago, read a paper entitled "Report of Cases of Chronic Heart-disease Treated by the Schott Method of Baths and Gymnastics." The baths are cool, saline, and carbonated, and owe their efficacy to chlorids of sodium and calcium. They are given at temperatures ranging from 92° F. in the beginning of the course to 87° F. later on. At first the bath lasts but five or eight minutes, and as the course proceeds finally reaches a duration of twenty minutes. The baths are given daily for three days, and omitted on the fourth. Every seance is followed by an hour's rest in bed, the patient being covered up warmly and permitted to sleep if so inclined. Such a balneologic course lasts about seven weeks, and then may be repeated after an interval of a month or so if advisable. The baths exercise a powerful influence on the heart, and therefore have to be ordered in strength, temperature, and duration in accordance with the indications present in the individual case.

From sphygmographic tracings taken before and during the bath the conclusion was deduced that these baths act on the heart similarly to digitalis. On the bloodvessels, however, their action was that of a vasomotor dilator rather than constrictor. At all events, whatever be their mode of action, they slow and strengthen the pulse, render it more regular when it is irregular, cause demonstrable diminution in the size of a dilated heart, and improve the character of the sounds if they are weak or impure.

The light exercises of the trunk and extremities that form a valuable part of the Schott method of cardiac therapeutics exert the same kind although not the same degree of effect as the bath. The peculiarity of these gymnastics lies in the fact that an attendant applies gentle resistance to the movements made by the patients.

Since November 1, 1893, Dr. Babcock has subjected nineteen unselected cases of cardiac disease to this form of treatment with most gratifying results. Thirteen received a full course of treatment, and of this number nearly all experienced more or less benefit. Improvement was generally noticed, first, in relief of dyspnea and of cardiac pain and discomfort. No medicines were administered except occasionally a mild laxative or some other simple remedy to meet a particular indication of transient disturbance.

Advanced degeneration of the cardiac muscle or vas-

cular system, as aneurisms and pronounced arterio-sclerosis, contra-indicate this form of treatment.

Dr. W. C. Glasgow, of St. Louis, read a paper entitled "A New and Distinguishing Sign of Latent Aneurism of the Aorta," consisting in the presence of a systolic bruit in the brachial artery. The patient extends the arm at a right angle to the body, and the auscultating ear is placed over the brachial artery, where a vibration of the artery, or a bruit, is heard in case of aneurism of the aorta. In no instance had the observation been confirmed by post-mortem examination.

Dr. J. B. Walker, of Philadelphia, related that he had noticed musical murmurs in the post-tibial which he had not associated with aneurism.

A paper entitled "Musical Nomenclature in Physical Diagnosis," by Dr. J. Hilyard Tyndall, of New York, was, in the absence of the author, read by title.

Dr. Charles E. Quimby, of New York, read a paper entitled "Ozone in Phthisis, with Special Reference to the Pneumatic Cabinet." He said that for a year his remedial agents in pulmonary tuberculosis consisted of alcohol, oil of cloves, and creosote.

He dwelt at length on the powerful oxidizing properties of ozone which he described as a stimulant to mucous membranes and a pulmonary antiseptic.

The use of these agents induces a prompt reduction in temperature and yields a result equivalent to climatic influences.

Fourth Day—June 1st.

Dr. Guy Hinsdale, of Philadelphia, read a paper entitled "The Comparative Rarity of Pulmonary Tuberculosis in the Highlands of Pennsylvania and the Adjacent Counties of New York." (See The Medical News, August 4, 1894.)

Dr. Samuel A Fisk, of Denver, Colo., read a paper entitled "Meteorological Data of Colorado." He referred at length to the many and well-known advantages of Colorado: its high elevation—one mile above sea-level; dryness of air, etc. He placed Denver among the cool climates. The winds were from the south and were dry.

Hon. Mark W. Harrington, Chief of the Weather Bureau, Washington, read a paper entitled "Sensible Temperature." By "sensible temperature" he meant that felt by the skin. On it depends the sense of comfort or discomfort in hot weather. High shade-temperature does not necessarily mean discomfort, if its dew-point is low. This temperature may be 127°, but the temperature felt by the skin may be 45° lower.

Dr. Judson Daland, of Philadelphia, read a paper entitled "Beri-Beri." He reported several cases studied at the Philadelphia Quarantine-Station. These occurred among a mixed crew on a vessel from the East Indies. The symptoms of the disease were attributed to a peripheral neuritis.

Dr. Albert L. Gihon, Medical Director U. S. N., deemed beri-beri a disease of malnutrition.

Dr. William H. Daly, of Pittsburg, expressed the opinion that the disease might be due to ptomaïn-intoxication as a result of digestive fermentation.

Dr. William H. Daly, of Pittsburg, read a paper entitled "Some Practical Observations on So-called Malaria." He concluded that the malarial germ is one of the infusoria, transmitted by impure water, in lowlands and swamps. The habitat of the germ is probably in the soil. The point was made that in malarial districts all escaped who drank pure cistern-water.

Dr. Wolfred Nelson, of New York City, related that in the island of Cuba gangs of men that slept by day and went to work at night on a full stomach never developed malaria; while the day-gangs, that slept at by night, when fogs and vapors were prevalent, developed malarial fever.

A paper entitled "Shock in Acute Disease," by Dr. John H. Musser, of Philadelphia, was, in the absence of the author, read by title.

Dr. W. C. Glasgow, of St. Louis, read a paper entitled "The Physical Signs of Cellular Edema of the Lungs considered in their Relation to the Pathological Changes." He maintained that cellular edema of the lungs is due to sepsis. The signs of the condition are at times very perplexing and contradictory. Infiltration occurs suddenly, and resolution may take place with equal suddenness.

Dr. Robert H. Babcock, of Chicago, said that the condition described by Dr. Glasgow resembled a form of broncho-pneumonia described by Dr. Delafield. The disease was in the walls rather than in the bronchioles.

Dr. Wolfred Nelson, of New York City, presented a series of photographs of the Grosse-Isle Quarantine-Station, in the St. Lawrence, below Quebec. He described the situation as an ideal one—an island in the lower St. Lawrence, twenty-four miles below Quebec, four miles from one and six miles from the other shore. It is a Canadian Government-Station. Forty buildings can be used for the reception of patients of all classes, from saloon to steerage. In a crisis, 3000 can be accommodated. It is the most extensive and modern quarantine-plant on this Continent. In twenty-four hours the effects of 1000 immigrants can be rendered absolutely sterile or safe.

Dr. F. Montizambert, the Superintendent of the Canadian quarantines is in charge. He has devoted his life to the work, and has made a study of all the American and Continental Stations. He is assisted by a large staff of trained assistants—medical and lay. Reference was made to the good work in sanitation done in this country by Dr. A. N. Bell and Dr. Joseph Holt.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Eighteenth Annual Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

Dr. George T. Jackson, of New York, read a paper upon "Thyroid Feeding in Diseases of the Skin," reporting three cases of xeroderma, one of ichthyosis, and one of dermatitis exfoliativa that had been treated with the desiccated powder, beginning with two grains at a dose in capsule. This was gradually increased. Unpleasant symptoms usually followed, such as headache, nausea, vertigo, etc. The skin, however, showed increased moisture and suppleness. No cure was obtained. Dr. Jackson said that he was not inclined to pursue the method further, as the results are not brilliant, and grave symptoms may appear.

Dr. Fox agreed with this conclusion.

DR. HARTZELL stated that he had seen no good effects from the use of preparations of thyroid gland.

DR. STELWAGON related that he had failed to secure benefit in psoriasis, dermatitis exfoliativa, and in pityriasis rubra pilaris. He had seen edema of the legs produced.

DR. HYDE had experimented on ten psoriatics; two showed decided improvement, two were made very ill, and in the rest no benefit could be observed. He had to record, however, improvement in a case of thyroid cachexia. He begins with a maximum dose and gradually decreases.

The next paper was by DR. G. H. FOX, of New York, on "Folliculitis Decalvans." This term he thought should include the greater number of those rare affections of the scalp which would appear to belong to the same general class of disease, but which are unquestionably not the same as the alopecia areata with which we are familiar. At first there is hyperemia and the areas are tender. The follicles become plugged up, and in the the more advanced stages depressed, pigmented cicatrices appear, with outlying separate follicles, indicating an extension of the disease to neighboring parts. These affected follicles become grouped and undergo the same changes, resulting in scar-tissue and consequent permanent baldness. Here and there nodules undergo suppuration, but acne is not a good term for the condition, although the term keratosis might be applicable to the follicular plugging. A ten per cent. salicylic ointment was recommended.

DR. ZEISLER had seen several such cases and called attention to the roughness of the patches from the broken off hairs.

DR. HYDE spoke of the possibility of tuberculosis of the scalp and peculiar forms of erythematous lupus, leaving cicatrices as they spread over the head. The disease cannot be simply inflammatory, or it would not result in scar-tissue. He reserved his opinion as to its true nature. Unguentum hydrargyri ammoniati had given the most satisfaction in his cases.

DR. SHERWELL had thought the disease might be a discoid lupus erythematosus.

DR. CANTRELL, of Philadelphia, read the next paper, on "Favus of the Head and Body," occurring in a young boy, showing scattered areas over the whole cutaneous surface coming on after the scalp had been affected for two years.

DR. JACKSON spoke of a case of favus of the body in which an herpetic-like ring was seen surrounded by typical cups.

DR. ZEISLER mentioned an instance presenting primary the lesions of favus upon the feet, occurring in a stableman accustomed to walking bare-footed about a stable infested with mice which probably had the disease.

DR. WIGGLESWORTH said he had experimented with Dr. White and had only succeeded in reproducing favus when the fungus was pricked into the hair-follicles.

DR. HYDE said almost any treatment was of benefit, but none could be called curative. A change from one form of treatment to another had given him the best results.

DR. SHERWELL spoke of several cases in a family in which the mice, as well as the dogs, were the sources of contagion. In one of the cases the lesions were upon the face.

DR. WHITE had seen favus of the glans penis. He contended that the disease is not an incurable one, as the numerous instances of baldness, without any sign of remaining disease, seen among Russian emigrants testified. In his practice there was one positive cure dating back fifteen years.

DR. HARTZELL mentioned Hardy's case of favus of the glans penis, in which, by means of a strong lens, a hair-follicle was found, showing it to be no exception to the rule that the part must be a hairy one to favor the growth of the fungus.

DR. ALLEN corroborated what Dr. White had said about cured instances in Russian Poles, although he had seen many instances among these immigrants in which the disease that had caused the baldness was more likely folliculitis decalvans. Until recently he had not had a case of favus of the body in his own practice, but he is now treating a mother and two children for favus of the scalp, and in one there is a lesion upon the lobe of the ear.

DR. W. T. CORLETT, of Cleveland, then read a paper upon "Cold as an Etiological Factor in Diseases of the Skin." A series of photographs were shown of cases presenting for the most part rounded lesions upon the forearms, backs of the hands, etc., which came on year after year, as a rule when the cold season was approaching, or in the winter time. Dr. Corlett believed that the influence of the climate in which his practice lay played a very important part in the production of this affection. The patches were mostly erythematous, slightly scaly, and showing little or no tendency to spread. Low temperature, air in motion, and humidity, were considered essential to its production. Though resembling in some instances herpes and in others eczema, Dr. Corlett looked upon the affection as a disease *sui generis* of the frost-bite variety, and would call it dermatitis hiemalis. Change of climate had given the best results, though suitable topical applications, and especially glycerole of tannin, had acted well.

DR. SHERWELL said some of the descriptions given suggested angiokeratoma.

DR. HYDE said all were familiar with the great influence of cold in some skin-affections, and he referred to his paper read at the Paris Congress on "Pruritus Hiemalis." Many other factors may be present. Lesions of the hands are always suggestive of infective diseases, and the gloves left over from the preceding cold season might contain the infective agent. He recommended parasiticides.

DR. WHITE would diagnosticate eczema if called upon to decide from the photographs. This, it is known, may be aggravated by cold.

DR. FORDYCE, of New York, followed with a paper on "Adeno carcinoma of the Skin starting in the Sweat-glands." A number of different pathologists have described cases of adeno-carcinoma originating in a a sweat-gland, but the number of cases in which this point of departure had been proved was very limited. In the present instance the growth had started as a proliferation of the columnar cells lining the sweat-glands, breaking through the membrana propria and infecting the surrounding connective tissue. The intra-cellular bodies which are looked upon by many pathologists as the cause of carcinoma were demonstrated, and a

belief in the parasitic nature of the disease expressed, though the exact etiology has not yet been made clear.

Dr. Stelwagon then read a paper upon "The Question of Contagiousness of Molluscum Contagiosum." A review of the literature of the subject was given, and the instances of seeming contagion or transfer from one individual to another were enumerated. In this way a large and convincing mass of evidence was presented and analyzed. The examples of spread in public institutions were very abundant. Accidental inoculations, as well as those experimentally produced, were related. The molluscbodies, it was thought, furnished the medium of contagion.

Dr. Hartzell did not look upon the so-called mollusc-corpuscles as external animal cells, but rather as altered cells of the body.

Dr. Zeisler had personally never seen a convincing instance of contagion.

Dr. White thought proof of the parasitic nature of the bodies essential.

Dr. Duhring believed the clinical evidence sufficient for us to regard the disease as surely contagious.

Dr. Hyde had never seen an instance of transfer from individual to individual.

Dr. Allen referred to an accidental inoculation upon his own finger after operating on a case. Two punctate tumors developed, and on removal, the microscope confirmed the diagnosis. Both auto-inoculation of neighboring parts and transfer to others were more active if a tumor had acquired some size, had softened, and perhaps suppurated. While small they seemed of little danger to others and were readily cured.

Dr. Fordyce showed the bodies in the cells, and one in the act of escaping. He said that while protozoa are not gaining in favor, as far as psorospermosis is concerned, they are as regards carcinoma and molluscum.

Dr. S. Sherwell, of Brooklyn, presented a paper on "Harlequin Fetus," relating an instance of this form of congenital ichthyosis, which is usually fatal, but which, in his case, had existed for six months already, with a prospect of the child's continuing its existence. He regarded the condition as one of defective development.

Dr. Zeisler mentioned inunction with any bland oil as a palliative measure. A cure was not to be expected.

Dr. Hartzell, of Philadelphia, presented a paper on "The Protozoa-like Bodies of Herpes Zoster," and considered their relation to those of psorospermosis. At a certain stage of the development of a zoster-vesicle certain bodies resembling protozoa are always to be found. Pfeiffer had first accurately described them, and Weigert had found them also in the pustule of smallpox. As the vesicle goes through its evolution the multiplication of the protozoa is rapid. They resemble in a striking way the epithelial cells containing coccidia found in the bile-duct of the rabbit. Dr. Hartzell had studied these bodies found in a case of recurrent zoster following the course of the sciatic, originating in traumatism. The conclusion is drawn that the appearances arise from alteration in the epithelium, and are not due to protozoa. The presumption is that the so-called psorosperms of the disease are metamorphosed cells. The enormous growth and peculiar arrangement argue for a process of vital activity, and not for one of degeneration.

Dr. White, of Boston, then read a paper entitled "Angioma Serpiginosum and Some Other Rare Dermatoses." Pityriaris rubra pilaris he looked upon as a member of the keratoses which called for special consideration. From his experience he would consider it more frequent than the statistics of the Society would seem to indicate. *Erythème induré des scrofuleux*, resembling erythema nodosum, but differing from it in its stage of softening and suppuration, when it suggested rather the gumma, was then taken up. The lesions are more deeply seated and more uniform than in erythema nodosum, and are not like bruise-marks. They may, however, be of a dusky-purple color, and those of longer duration brownish; some become depressed, leaving disclosed cicatrices, while other disappear leaving pigment-stains only. The so-called scrofulous gumma is often strongly suggested. Remarks upon multiple benign cystic epithelioma were illustrated by a photograph showing some fifty lesions in various stages upon the face. There were flat papules having the normal color of the skin, some lesions with sunken centers, others showing crusts, while some appeared as elongated ulcers. Two such were especially noticeable near the eyes, and appeared like rodent ulcers. There were no subjective symptoms. Some had taken on the ordinary features of epithelioma. A case of angioma serpiginosum had occurred in the person of a boy, the lesions extending from the right scapula to the nipple-region as a belt three inches wide. There was an elevated creeping margin to the lesions, which was of uniform breadth and firm and smooth. The name given by Crocker was considered more appropriate than that originally suggested by Hutchinson, infective angioma. Dr. Councilman, of Boston, together with Dr. Bowen, had made histologic examinations, and they had agreed upon the name angio-sarcoma as best fitting the conditions presented.

Dr. C. W. Allen, of New York, followed with a paper on "Acquired Idiosyncrasy for Quinin, showing Peculiar Cutaneous Manifestations." A man who had previously always been able to take quinin developed his first eruption from five grains of the sulphate, and for a number of years had the same erythematous spots in the same locations whenever the smallest quantity was given by mouth, rectum, or through the skin. With the consent of the man, Dr. Allen carried out a series of experiments extending over several years, to determine if possible the manner in which the drug acted to produce this effect. The conclusion reached was that the drug affects primarily the cord in the upper dorsal region, and he thinks that this, if verified, may lead not only to a clearer understanding of certain skin-diseases of obscure origin, but may also explain how quinin acts to produce some of its therapeutic effects.

Dr. E. B. Bronson, of New York, then gave the history of "A Case of Symmetrical Cutaneous Atrophy of the Extremities." The subject of this rare condition was a male, forty-five years old. The left ankle had first become affected fourteen years ago. From here there was a gradual extension to other regions. The knees now present a peculiar wrinkling of the skin, the folds occurring in the natural lines of cleavage. In all the atrophic areas the blue vessels shine through, giving a lilac hue. These regions are more sensitive than the normal skin. The disease is regarded as spontaneous and idiopathic. The legs and lower third of the arms

are the parts most affected. The hairs have almost disappeared from the implicated regions and sweating seems to have ceased.

DR. ZEISLER, of Chicago, presented a paper upon "The Relation of Impetigo Hepetiformis to Pemphigus Vegetans." The features common to these two diseases are very striking. Both, too, occur mostly in women and begin upon a mucous membrane. The lips were first affected in a case reported. Deviations from the type must be considered possible, and a case should not be thrown out of either category because in some unimportant detail it does not correspond with the original description. For a positive diagnosis either disease must be observed carefully from beginning to end, which in both is a fatal one. Among the many points of similarity pointed out were the etiology and pathology, about both of which nothing is known. Vegetations are not always present from the outset, but appear where moisture, friction, and warmth favor their development.

DR. GILCRIST, of Baltimore, by invitation, read an interesting paper entitled "Protozoan Dermatitis." He related the first case of the kind recorded in this country. The protozoa were shown under the microscope. They were very numerous, sixty sometimes being in the field. Twenty had been found in one giant-cell. A dog had been inoculated, the same disease reproduced and protozoa being found. Dr. Gilcrist considered the bodies found as belonging to the vegetable rather than to the animal kingdom.

DR. DUHRING showed photographs of a case of generalized sarcoma sent by Dr. Breakey, of Ann Arbor.

DR. BRONSON presented a new dermal curet and comedo-expressor.

The Association then adjourned to meet in Montreal, Canada, in September, 1895.

NEWS ITEM.

The Cholera and the Plague.—It is reported that cholera is epidemic at Canton, China. The plague is still raging among the natives and does not seem to yield to treatment, the mortality reaching 90 per cent. Forty-thousand deaths are said to have occurred at Canton since March 1.

Five new cases of cholera and three deaths were reported at Maastricht, in Holland, on August 5th and 6th. Five cases and two deaths were reported at Halfweg and one death at Haarlem.

On August 7th two deaths from cholera occurred in Amsterdam and one in Dordrecht.

Three new cases and two deaths were reported in Maastricht on August 7th.

In the six days immediately preceding August 4th there were 313 fresh cases of cholera and 240 deaths in St. Petersburg. In the six days preceding July 28 there were 159 fresh cases of cholera and 83 deaths in Warsaw.

For the Department of Warsaw the reports for the same period record 394 fresh cases and 213 deaths. All these figures covered only the reported cases.

On August 7th the captain of a steamship which arrived at Gravesend from St. Petersburg reported that one of his crew died of cholera during the voyage.

THE COLORADO CLIMATE FOR TUBERCULOUS PATIENTS.[1]

BY WILLIAM P. MUNN, M.D.,
OF DENVER;
MEMBER OF THE COLORADO STATE BOARD OF HEALTH.

IT may be regarded as proved that tuberculosis of the lungs can not only be recovered from, but that some cases make a perfect recovery without the disease being either recognized or subjected to medical treatment. With this premise made and admitted, it is not incorrect to state that the problem of cure or arrest should assume as great importance as the problem of prevention.

The factors of the problem of cure or arrest are: (*a*) On the one hand, the resisting power of the organism and the influences or conditions that tend to modify that resisting power. (*b*) On the other hand, the virulence or activity of the specific organism causing tuberculosis and the influences or conditions that modify it, and retard or assist its development, either without or within the body.

The most influential factors, both of assault and resistance, are those of environment, and chief among the elements of environment come climatic influences. Equally important, from one point of view, is the environment of occupation, of clothing, and of personal habits; but the correction of faulty conditions in these regards, unaccompanied by climatic change, is likely to be futile in a large majority of cases. The accumulated and disastrous experience of generations of effort proves this most conclusively. Until climatic environment is made favorable, the human organism is at a disadvantage in its battle against the microörganism and those concomitants now almost universally believed to be the cause of tuberculosis.

The study of the bacillus tuberculosis and its life-history has resulted in the discovery of facts that go far toward explaining climatic influences long since appreciated, but not thoroughly understood. For example, it was early observed that the inhabitants of high, dry regions did not acquire pulmonary tuberculosis. We now know that this is because the bacillus loses its vitality forever when thoroughly dried in the direct sunlight of high altitudes. It has been observed that the children born in such regions, of markedly tuberculous parents, are to a remarkable extent exempt from tuberculosis. We now know that this is so because the elements of infection usually transmitted from parent to offspring through the air are, in high, dry regions, rendered harmless while in transit, and we know, too, that this very fact has alone finally controverted and destroyed forever the fallacious belief that tuberculosis is an hereditary disease, transmitted from parent to offspring in genesis. And if that misleading belief should ever prevail again it ought to be negatived absolutely and for all time by the army of robust, healthy, non-tuberculous men and women now in and coming to adult life in the State of Colorado, who are the children of tuberculous parents, and who have been protected from the direct contagion of their parents' disease by climatic environment favorable to their own physical development and unfavorable to the microörganism of tuberculosis.

But the prevention of the development of tuberculous disease, while the great desideratum for the coming generation, does nothing to relieve the patient now suffering from pulmonary tuberculosis. To such invalids medical science has heretofore offered small encouragement of recovery by the use of therapeutic meaures. Change of climate has been the one procedure offering most hope, but this has been recommended in an indiscriminate, or rather, an undiscriminating manner, indicative of lack of appreciation of the true factors of climatic environment that are desirable or beneficial. New countries have always been most highly lauded as places of residence for those suffering from chronic pulmonary disease, and as the country became more settled such places have, as a rule, lost their repute. In the last century New York was the popular resort for cases of this character; later, Ohio, Michigan and Minnesota, North Carolina and Georgia, attained some reputation as health-resorts for tuberculous patients, but failed to maintain their reputation. It has even been said that as this is the common lot of all newly-settled countries, so the eastern slope of the Rockies will, in time, also lose its reputation, and that tuberculosis will make its permanent habitat there also. From any such opinion I dissent. That region presents conditions other than the purely negative one, common to other newly-settled countries, of freedom from the cause

[1] Read before the Forty-fourth Annual Meeting of the Medical Society of the State of Pennsylvania, May 17, 1894.

of tuberculosis until such time as increase of population brings the cause to the country as a permanent entity.

Anti-tuberculous climatic conditions (*a*) prevent the development of tuberculosis and (*b*) exercise an ameliorating or curative influence upon already existing tuberculous lesions.

These favorable climatic conditions are as follows: (1) dryness, (2) sunshine, (3) purity of atmosphere, (4) rarity of atmosphere, within certain limits, (5) equable and moderate temperature. These favorable conditions exist in an exceptional degree and over an extensive territory upon the eastern slope of the Rocky Mountains, in the State of Colorado.

The invalid suffering from pulmonary disease finds much difficulty in obtaining from his medical adviser reliable information or valuable advice in regard to the region in which he is to seek natural conditions that will retard his disease or effect its cure. For this reason I feel that it is an eminently proper thing at such a meeting as this to state as succinctly as possible the climatic advantages of Colorado and to indicate the class of patients that my own experience has shown may be benefited by residence there.

It may not be out of place to bear my personal testimony to the fact that residence in Colorado does retard or cure pulmonary tuberculosis. As an example of the frequency of such cures I may cite the fact that there are forty physicians having offices within a block of my own residence in Denver, and of this number twelve, or 30 per cent., were tuberculous prior to coming to Colorado, but are now in vigorous health and engaged in active practice. Five more of the forty are in Colorado because their wives became tuberculous in the East; all are now in good health. While the same ratio may not hold good for our entire population, it is a fact that an unusually large number of persons formerly tuberculous, and now healthy and vigorous, are to be found in Denver and its sister cities and towns. It is not an exaggeratian to state that probably one-fourth of the population of Colorado came to the State originally because of pulmonary disease in themselves or some member of their families.

Briefly stated, the desirable climatic conditions in Colorado are as follows: 1. *Dryness.* Years ago. this element of our climate was so misunderstood and over-estimated that the whole 103,000 square miles of our area was considered to be desert land—sandy, uninhabitable, and unfertile. This misapprehension was based upon the lack of rainfall. The rainfall is, indeed, inconsiderable, especially when compared with that of the Atlantic coast and of the Ohio and Mississippi valleys. In Denver, for example, the average total annual precipitation for twenty years, which includes both rain and snow, has been but 14.5 inches; in New Haven, Conn., it is 50 inches; in Washington, D. C., 44.8 inches; in Atlanta, Ga., 55.9 inches; in Jacksonville, Fla., 56.3 inches; in Chicago, 36 inches; in New York, 45 inches; in Philadelphia, 41.2 inches; in the State of Washington there are points where the precipitation is 92 inches per annum; and in such foreign resorts as Florence, Italy, it is 41 inches; in Genoa, 47 inches; in Geneva, 32 inches; in Naples, 30 inches; and in Algiers, 27 inches. The wettest place on earth is Assam, Asia, where the average annual precipitation is 610 inches, and in 1861 it was 905 inches. The average rainfall for the whole world is said to be 36 inches per year. When these figures are considered, it is readily seen that Denver, with 14.5 inches rainfall per year, is, relatively, quite a dry location, and it must be remembered that Denver has, perhaps, the greatest amount of precipitation of any location in Colorado. In Montrose, Colorado, there is but 8 inches rainfall in the course of the year. There are certain comparatively inaccessible locations in the United States having drier climates, *e. g.*, Yuma, Arizona, with but 3 inches rainfall per annum, than which there is but one lower record for the whole world, Port Saïd, with the burning winds of the Arabian desert passing over it, which has but 2 inches annual rainfall.

The therapeutic value of a dry atmosphere is twofold: (*a*) It antagonizes the vitality of the bacillus; (*b*) it takes up more moisture from the lungs in respiration, thus removing a greater amount of the toxic results of respiration, and lessening the volume of expectoration; (*c*) it assists elimination from the skin, promotes thirst, and by thus stimulating the patient to fill his bloodvessels promotes the activity of all the emunctories.

In considering the dryness of the Colorado atmosphere, we usually speak, as I have already done, of the rainfall only. A much more valuable observation is that of relative humidity. This means the comparison of moisture actually held in suspension in the air with the amount which it can hold (complete saturation) at existing conditions of temperature and pressure. Manifestly an atmosphere of low relative humidity will more readily cause evaporation from the body, and along with the moisture thus removed go the other organic impurities resulting from respiratory oxidation. A comparison of the relative humidity of Denver and of some Pennsylvania cities and of New York City for the years 1891 and 1892, and of Denver for 1893, is here appended.

	1891.	1892.	1893.
New York City .	75 per cent.	72 per cent.	
Harrisburg . .	70 "	73 "	
Pittsburg . . .	70 "	69 "	
Philadelphia . .	70 "	70 "	
Denver	51 "	51 "	43.7 per cent.

In studying the relative humidity of different cities by months, it is of especial note that the greatest humidity of our Eastern cities is observed in July and August, when the relative humidity of Denver is at its lowest. The period included between the months of February and May is that of our greatest relative humidity, but even these months are drier than the driest months of the cities of the Atlantic coast and in the Ohio and Mississippi valleys.

Great interest attaches to this subject, and it is worthy of more extended study than is possible within the limits of this paper.

2. *Rarity of atmosphere.* This condition varies, of course, with altitude. In its 103,000 square miles of territory—an area almost as great as that of Italy, half as large as France, and seven times that of its great climatic rival, Switzerland—Colorado presents an unsurpassed range of altitude, from 3000 feet above the sea-level on the east, to 15,000 feet, among the peaks of the Rocky Mountain range. The broad, high plateau on this side of the mountains rises so gradually that, while it seems almost level, it yet attains at Denver, which is twelve miles distant from the foot-hills of the Rocky Mountains, an altitude of one mile above the sea level. The altitude of Colorado Springs is 6150 feet; that of Manitou, 6500; of Boulder, 5300; of Brighton, 4900; of Greeley, 4500; of Pueblo, 4800; of Morrison, 5700. Along Platte and Clear Creek Canons are very many pleasant little mountain-resorts at altitudes varying from 6000 to 9000 feet. Estes Park and South Park are great natural parks whose altitudes range from 6000 to 8000 feet. On the west side of the continental divide Glenwood Springs is at the same altitude as Denver, and presents natural advantages superior to the Hot Springs of Arkansas or to any of the great baths or resorts of Europe. Leadville is 10,000 feet above the sea; Cripple Creek is at about the same altitude.

This cursory statement of the wide range of altitude easily accessible, and at points providing ample accommodations for invalids, gives but the faintest idea of the range of location open to the invalid searching for an altitude best suited to his individual case.

The rationale of the beneficial effects of rare atmosphere is, of course, simple. The amount of oxygen necessary for respiration can be found at high altitudes only in larger quantities of air than at low altitudes. The effort to obtain this causes deeper inspirations, and, as a result, unused or partly solidified areas of pulmonary tissue are opened up by the natural and unstudied efforts of the organism. Theoretically there is much to fear from this effort, especially in patients who have had hemorrhages. Practically this fear has been proved to be quite baseless, except in those whose disease has advanced so far that there is not enough available air-space left in the lungs for free respiration at any altitude. Especially worthy of note is the fact that altitudes of less than 8000 feet are only exceptionally dangerous for hemorrhagic cases; and that, as a rule, if such a case does not improve at 5000 or 6000 feet, it will improve if taken higher after a time. Patients whose progress has been slow in Denver (at an elevation of 5200 feet) have improved more rapidly after a year or two, on removal to Idaho Springs (at an elevation of 7500 feet), Georgetown (at an elevation of 8400 feet), or Leadville (at an elevation of 10,185 feet).

3. *Sunshine.* Reliable sunshine-statistics have not been accessible until within the last two years. This has been partly on account of defective equipment of observers, and partly on account of defective methods of stating the results of observations. What constitutes a sunshiny day has always been a matter of dispute. In 1891 the weather-service adopted the method of making photographic notes of actual hours of sunshine. The records are now beginning to be of value, although the limited number of stations at which such observations have been taken interferes with any extensive comparison. In 1892, Philadelphia had, approximately, 2263 hours of actual sunshine out of a possible 4618 hours—*i. e.*, 49 per cent. of the possible sunshine. In the same year Denver had 2858 hours of actual sunshine out of a possible 4594 hours—*i. e*, the sun shone brightly during 62 per cent. of the time that it was possible. The difference between 49 per cent. and 62 per cent. of sunshine is relatively enormous. The actual excess of hours of sunshine in Denver over Philadelphia approximates almost two hours every day in the year. To the tuberculous patient this extra amount of sunshine means very much in increasing the daily time during which he can remain out of doors. And it should go without saying that out-of-door life is what every tuberculous patient ought to have. It is ridiculous to travel hundreds or thousands of miles for the benefit of disease by climatic environment and then to coop oneself up in rooms in which the artificially generated conditions are probably as bad as, or worse than, those of the home from which one has removed.

Many unfortunate terminations might be avoided if pulmonary invalids knew enough to take proper advantage of natural conditions. Out-door life, fresh air, and sunshine, are the great requisites, more efficient in Colorado than in most other localities in this country, but of benefit everywhere, if taken advantage of with intelligent persistence.

For this reason most Colorado physicians recommend their tuberculous patients to seek a residence in the suburbs if they remain in Denver, but as a rule to get out of the city if possible. Life on a

ranch or in a mining-camp is preferable to life in a city, if one can only secure the necessities and a few of the luxuries of life. The incipient tuberculous patient who deliberately gives up his regular occupation or profession and goes to "punching cows" for two, three, or four years, is practically certain to effect a permanent recovery, and to gain as well a unique experience as valuable to him as his restored health will be.

These observations comprise a plain statement of actual conditions existent in Colorado, and indicate advantages that will inure to the pulmonary invalid, or "lunger," in semi-facetious Western phraseology, from a residence there.

A disease so essentially chronic in its nature and progress as pulmonary tuberculosis is not susceptible of a *rapid* cure, even under most favorable climatic influences, and in individuals having large natural powers of resistance to the disease. Hence those who attempt its benefit by a change of climate must not expect a radical cure after a short residence in Colorado. It is not unusual to have patients sent us from the East, with the assurance of their home-physicians that a residence of a few months, or at the longest a year, will permanently restore their health, so that they may safely return to their Eastern homes and resume their ordinary occupations. No more fallacious idea could ever be advanced. No assurance could be so utterly unfounded. And yet we meet almost daily with invalids who have come to us holding firmly to this erroneous belief, and who persist in clinging to it in spite of all argument or of iterated or reiterated proof, simply because their physician at home "told them so."

The fact of the matter is that, although we speak of climatic influences effecting a cure, their action is not strictly curative, but they simply tend to retard or arrest the progress of the disease. Some infiltrated areas may, and indeed do, open up again, become pervious, take part in respiration, and finally become perfectly healthy, but the greater part of the pulmonary tissue that is already involved remains so. It is isolated—the disease-process is no longer aggressive, but it is put on the defensive, its area slowly lessens, its infective element dies, and finally fibrous change sets in, converting the enemy's camp into an innocuous ruin.

Under favorable environment the constitution triumphs, but it is not strictly accurate to denominate this triumph as a "cure;" it is a recovery—and a recovery that takes time. From three to five years constitute the ordinary duration of a fatal case of pulmonary tuberculosis. From three to five years constitute the ordinary duration of the process of recovery under favorable climatic conditions. True, there are exceptions, both as to rapidly fatal cases under unfavorable circumstances and rapid recoveries under favorable circumstances. But rapid recoveries are far more rare and far more difficult of demonstration than are rapidly fatal cases.

Now what is the practical meaning of this statement of the time necessary for recovery? It means, for nineteen out of twenty—yes, for ninety-nine out of a hundred—who make change of residence to bring about this recovery, that *the change must be a permanent one*. Five years in a new country mean, for all who are not exceptionally fortunate (or unfortunate), new social and business relations that may preclude the possibility of return to the old home, or that, at least, render such return inadvisable. Then, too, we must remember that return means, too often, resumption of former occupations, renewal of old habits, entrance into old surroundings, which are unfavorable and which tend to cause a second attack, as they probably contributed to the first one. And the universal verdict of Colorado physicians of wide experience is that second attacks of tuberculosis—it would be more accurate to call them relapses—following apparent recovery due to residence in Colorado are rarely recovered from. Time and again our patients who imagine themselves entirely well because a few months have elapsed without serious symptoms, insist upon returning to their Eastern homes to arrange business affairs, to make visits, or to resume their occupations. Arguments, protests, and warnings are without avail, the return trip is made, the predicted relapse occurs (usually disguised as a "cold"), and before the season is out they are back with us, vainly seeking for the second time the gratifying improvement that occurred during their first visit.

We see very many of another class of patients—those who, with far advanced disease of both lungs and with death so plainly stamped upon their faces that the most casual observer could make the correct diagnosis and the certain prognosis, are sent away from home, relatives, and friends upon an illusive chase after strength and health. Patients with their respiratory area so lessened in extent have the inevitable end only hastened in our rarer atmosphere. And far worse is the fact that such fatal results frequently deter really suitable cases from making the essential change of location. It is a regrettable truth that physicians are in many instances responsible for such exhibitions of bad judgment. Another regrettable truth is this: that the diagnosis has in many cases been inaccurate. Indefinite "lung-trouble," "bronchial catarrh," "catarrhal cough," simple "laryngitis," are among the disease-names that we find have been applied in a majority of instances to undoubted cases of pulmonary or laryngeal tuberculosis.

Many patients of this class make a short visit to

Colorado in spite of the advice of the physician at home, who assures them of a perfect recovery if they "take medicine." Their surprise upon discovering actual disease of the lung as a rule only equals their surprise at having the entire thorax examined by percussion and auscultation. Many a tuberculous patient who has "suffered many things of many physicians" gets his first sight of a stethoscope in Colorado—an explanation of the failure to recognize pulmonary tuberculosis earlier in many instances, and a sad commentary upon the careless methods of examination even by capable physicians.

It would not be proper to close this paper without mention of a class of patients that, either from lowered resisting power or because of concentration of the specific pathologic factor, do not recover in Colorado, although they come as early as possible and follow as conscientiously as possible the most approved methods of life and treatment. These cases are not infrequently seen. They belong probably to the class that in unfavorable environment would be denominated acute pulmonary tuberculosis, or in common phrase "quick" or "galloping consumption." Although the climatic influences are not potent enough to permit patients of this class to recover, the favorable conditions do exercise a retarding influence upon the progress of the disease. Not uncommonly persons whose condition is such that six or eight weeks would be the utmost limit of life in a humid atmosphere at a low altitude are enabled to live in comfort and to enjoy life for from six months to two years in the dry, invigorating atmosphere and warm sunshine so constantly present at an altitude of from 5000 to 7000 feet. Such a prolongation of the vital forces means very much to many invalids, and yet this class represents but a fraction of the great and constantly increasing number to whom Colorado climate has brought new health, new vigor, and renewed usefulness in their vocations in life.

A NEW WOOL-TEST FOR THE DETECTION OF COLOR-BLINDNESS.

By WILLIAM THOMSON, M.D.,
of Philadelphia;
Professor of Ophthalmology in Jefferson Medical College; Surgical Expert to the Pennsylvania Railroad Company, etc.

The new test herewith presented is based upon and is a simplification of and improvement on the "color-stick," an arrangement of wools adopted by the Pennsylvania Railroad Company in 1880, and described in their instructions for the examination of their employés, and further in The Medical News of January 14, 1882; in the *Diseases of the Eye*, by Nettleship; and in the *Popular Science Monthly* for February, 1885, under the title of "A Practical Examination of Railway Employés as to Color-blindness, Acuteness of Vision, and Hearing."

The entire system has been continued on the Pennsylvania Railroad unchanged, giving full satisfaction, and is used as a barrier before every new employé to protect the road from the admission of dangerous men. It has been adopted by the Philadelphia and Reading Railroad Company and by others, as is shown by the replies received in response to a circular recently sent to a hundred of the most important railroad corporations of this country, controlling 129,970 miles, asking if examinations were made as to color-blindness. Thus, it was found that

Those using Dr. Thomson's test controlled	38,786	miles.
Those using other methods controlled	15,679	"
Those making no test controlled	29,428	"
Those making no reply controlled	46,077	"

Sixteen other roads having control of 12,947 miles have also adopted my color-stick, thus making a grand total of 51,733 miles protected by this test out of 142,917 covered by the investigation. The total number of roads included is 116; of these 40 use my color-stick; 11 use other color-tests, mainly Holmgren's; 31 use none; 34 have made no response. The entire system has also been in use on the Midland and on the London and Southwestern in England.

The Pennsylvania Railroad system has accomplished much good, but there is yet much to be done to bring all the roads in the country under the protection of some efficient method of testing, to secure both the roads and the public against loss of life and property from these well-known defects of their employés. The total mileage of the country is 175,233 and there are 1,000,000 employés.

The protection of over 50,000 miles of track by one system is an efficient answer to the charge from England, where the total trackage is but 19,288 miles, that nothing had been done in the United States beyond the passing of a law in the State of Alabama on this subject.

As the result of much experience, and after a recent study of the entire subject, I would suggest some improvements that will enable a new test to be used in connection with the color-stick or as a substitute for it. The color-skeins of this new arrangement have been most carefully selected, and a standard set will be kept, so that renewals may be made of the entire set or of those skeins that may become faded, soiled, or lost. The new set consists of a large green and a large rose test-skein, and forty small skeins, each marked with a bangle having a concealed number, extending from 1 to 40, placed in a

double box, so arranged as to keep the two series apart and to permit each to be exposed upon a table in a confused mass. The stick is dispensed with, as giving too fixed an arrangement to the skeins and not enough *confusion*, although the skeins could be readily removed from their hooks and changed in position for this purpose.

The large green skein being placed near by, the small skeins from one to twenty are exposed in good daylight, and the employé under examination is directed to select ten shades of the same color of the test-skein. One with normal vision will choose promptly and with ease the ten greens with odd numbers on the bangles. A color-blind person will hesitate, and his selections will contain some even numbers, and the confusion-colors will be shades of brown, etc., containing some red, or shades of gray, and will indicate the color-defect. These figures are to be recorded on a blank, and the twenty skeins are to be removed. The large rose skein is then used and the examination repeated in like manner with skeins numbered from 21 to 40, and the result recorded. The confusion-skeins, which have even numbers, are blue, green, and gray. From the selections made by the man found color-defective by the green-test, we are able to decide the character of his color-blindness. Those selecting blues are red-blind; those taking greens and grays are green-blind, according to the nomenclature of Holmgren. There are ten roses and ten confusion-colors in the second series.

The red test-skein of the stick, with its confusion-colors, is omitted entirely, and the test is made to conform more strictly with Holmgren's method, while the examiner is also provided with forty questions of decisive clearness. Greater scientific accuracy is obtained by this method, and with the careful selection of these confusion-colors I now regard this system as an improvement upon the stick, and as a safer and more simple method to be used by a non-professional examiner. The blank will also give to the division superintendent or to any supervising surgical expert a more simple report of the examination. The yarns are to be kept from the light in the double box, one side of which is colored green and the other rose, to aid the examiner in keeping the series separate and to save time. The test will be a valuable addition to those to be used by surgical experts.

In order to show how the Pennsylvania Railroad Company keeps its records of these examinations we submit the following fac-simile of an actual blank:

WEST JERSEY RAILROAD COMPANY.

CAMDEN, January 19, 1883.

NOTE.—Those approved, marked "Appd."
Those not approved, marked "Not Appd."

It may be of service to present to the surgical experts in charge of the examinations of the various railroads the means that I have adopted for my own guidance in giving my final decisions. From the numerous methods described by scientific authorities I have selected ten that are practical, simple, and especially fitted for the detection of color-defects in employés of railroads. A book of record should be kept in which each case, with the results of the testing, should be entered. The Pennsylvania Railroad

system provides that the preliminary examination should be made under the direction of the division-superintendent by non-professional examiners, but it is to be under the supervision of one professional competent surgeon, who is known as the surgical expert, who becomes responsible for the qualities of the tests, and who gives the final decision in all cases referred to him. Thus the men are protected from the errors of lay-examiners, and do not lose their places until pronounced defective by professional authority. With ordinary care no color-blind man should escape detection by the lay-examiner, but men really fit for the service might be unfairly treated.

When referred to the expert the man found color-blind will present himself with the blank of his examination, and the surgical expert will then corroborate this by the following means:

1. The stick or the new test-skeins; or both.

2. Holmgren's set of one hundred of fifty various-colored skeins will be used and the proportion of mistakes recorded.

3. Browning's pocket spectroscope will then be used, and the man be directed to describe the colors he sees when looking through the instrument. If color-blind he will say that he sees but two colors, yellow and blue, with a gray or a neutral band between then.

4. The color-tables of Stilling will then be used; these are so arranged that on a colored background letters and figures are printed in the confusion-colors of this background so as to be indistinguishable by the color-blind.

It now becomes requisite to test the central vision, and to determine the power to perceive the signal-colors that are used by night.

5. A piece of dark cobalt-blue glass should be used in the trial-frame over each eye separately, and the man be directed to look at the flame of a candle or other small light, from a distance of twenty feet. An eye normal in refraction and color-sense sees the light, colored rose or pink, surrounded by a blue halo. To a hypermetrope there may be a blue light, with a ruby-colored ring or halo; but two colors will always be seen, whilst the color-blind man sees but one color, blue, or a light spot with a blue halo.

6. Donders' instrument has a standard candle in a dark cylinder, with a wooden disc, and pieces of red, green, blue, and white glass so arranged as to be rotated in turn in front of the flame. Here also there is a metallic slide, with perforations ranging from one to twenty millimeters in diameter. The man is placed five meters away, and while the colors of the light are changed by rotating the disc he is challenged to designate the colors of the transmitted light. The normal eye recognizes them through the 1 mm. opening at 5 m.; or, better still, the candle is so placed that the examiner with normal color-sense just perceives the color through the 1 mm. opening at 5 m. The color-blind individual may fail through a series of openings until the 20 mm. one is presented. He may still call white green, and red green. If so, he is asked the significance of the green, and answers "caution." He is then requested to approach the light slowly, and as he does this he may perhaps at one meter or one-third of a meter, by its intensity or size, recognize and call it red. Using the same ratio for his color-blindness as we employ for his acuteness of vision, we can reason thus: Full color-sense enables one to see the lights promptly at 5 meters through the 1 mm. opening; if the man sees them only after the apertures have been increased, his color-sense must be defective. Thus, if an opening of 20 mm. is needed, the color sense $= \frac{1}{20}$; should the man fail with the 20 mm. opening at 5 m. he is told to approach it, and if he sees it at 1 m. he has $\frac{1}{100}$ of color-sense, and if at $\frac{1}{3}$ of m., or 1 foot, he has only $\frac{1}{300}$ of the normal power. The mere diminution of white light, by interposing pieces of London smoke, may induce the color-blind to pronounce it in turn white, green, and finally red.

7. A tin lantern, with a switchlight condenser having a four-inch opening arranged so as to admit of placing pieces of white (ground), green, red, blue, and London-smoke glass before it, is now employed. This could also be made to take the place of Donders' instrument, if covered with a front, and with a sliding-piece with small perforations. A man failing to recognize the light from a four-inch aperture leaves no possible room for doubt, and this fixture is useful in convincing the friends of the man, and any railroad officers who may desire a rude test. The light is in diameter 100 mm., and should be seen at 500 meters.

8. The instrument of Mr. Carter, of London, is then made use of. This is to guard the surgical expert against a hasty opinion, and is to act as a check upon all wool-tests. It is based upon the sensibility of the retina and its power to recognize form and color in various intensities of light. The surgeon and the man examined regard the tests simultaneously while the quantity of light is varied; thus, possible errors with other tests, especially Holmgren's, can be avoided.

9. In Dr. Chibret's instrument, by means of polarized light various colors may be produced at will. The color-blind betray themselves by placing the instrument so that two dissimilar discs of light appear to them alike.

10. Finally, an assortment of flags that have been in actual use, ten of each color, white, green, blue, and red are used as a test. These are thrown

down in a confused mass on the floor, and the man is directed to properly assort them. Astounding mistakes are often made; as, for example, when a man is directed to take a red flag and use it to protect the rear of a train, he may select a green one.

A profound understanding of this curious defect of color-perception must be acquired to enable the surgical expert to make the best use of these various methods, and whilst they are sufficient they are decisive and require but little time. Perhaps the transcript of one case from my record-book may illustrate these brief descriptions:

J. H., employed by the Pennsylvania Railroad Co., forty three years old; found defective, and referred for final opinion.

Color-stick: With green, selects Nos. 1, 2, 3, 4, 6, 7, 11, 13, 15, 17; with rose, selects Nos. 22, 25, 21, 27, 28; with red, selects Nos. 31, 32, 33, 34, 37.

Holmgren: Green, selects 2 greens and 21 confusions; rose, selects 5 greens, with 13 confusions; red, selects 8 greens, with 9 confusions, 2 greens.

Donders: Fails at 5 m. on all apertures; fails at 1 m. on all apertures; ⅓ m. on all apertures.

Calls, with 20 mm. opening, green red; red green, and white, light-red.

He made more mistakes than successes, with gray (London-smoke glass) over white; called it red and green, as light was increased or diminished, and finally declared that he had never seen such lights on a railroad.

Failed with switchlight, 4 inches in diameter, at 5 m. and at 1 m., and manifested a color-blindness or defect greater than $\frac{1}{300}$, as he failed to see at 1 m. what a normal eye would recognize infallibly at 500 meters.

Cobalt-glass: Sees white light with blue halo; no red or rose.

Flags: At 1 m. calls dirty-white green; fails to distinguish red from green. He was then told to select from a pile of flags the danger-signal, or red one, and to hurry back and protect his train; with his own hands and deliberately he chose six—three red, two green, and one blue—stating that "they would all stop trains."

Stilling's tables: Fails in all but VII, which should be recognized by a color-blind.

Pronounced color-blind and unfit for any duty in which he would govern his actions with color-signals.

I will conclude by urging the need for reëxaminations at stated periods, and in individual cases when a man has been injured, or has recovered from a serious illness, or when he uses tobacco or alcohol to excess.

The test here described can be obtained of Queen & Co., of Philadelphia.

The Twelfth International Medical Congress will be held at Moscow in August, 1896.

THE TREATMENT OF ACRO-PARESTHESIA (NUMBNESS OF THE EXTREMITIES).[1]

By WHARTON SINKLER, M.D.,
of Philadelphia;
Physician to the Infirmary for Nervous Diseases and Neurologist to the Philadelphia Hospital.

In 1884 I read before the College of Physicians of Philadelphia a paper on a form of numbness which occurred principally in the upper extremities; and my observations showed that it was usually met with in women at about the change of life, although it occasionally occurred in men. I regarded it as a vasomotor neurosis, because of the circumstances under which it was most likely to occur, and because it seemed to be one of the annoying symptoms which belonged to the menopause. Dr. James J. Putnam had already described some cases of the same kind, and suggested that the affection was probably due to alteration in the blood-supply of the terminal nerve-branches. Omerod, who had also written on numbness of the extremities, believed the condition to be allied to Raynaud's disease, and probably the result of vascular spasm.

"Waking numbness" is a condition which has been recognized for years, and recently several articles on paresthesia of the extremities have appeared. The view now generally held in regard to this disorder is that it is a form of peripheral neuritis. Collins[2] has recently presented an interesting paper on this subject, and analyzes forty-three cases of the affection. He holds that the trouble is due to defective innervation of the bloodvessels, which causes a low degree of blood-pressure and lack of proper blood-supply to the terminal branches of the peripheral nerves. He thinks that the most striking factor in the etiology of the affection is occupation, as he found that 75 per cent. of his patients were women who did either washing, sewing, scrubbing, or needle-work of some kind; and he believes that bodily fatigue, over-exertion, and poor nourishment are predisposing factors.

Schultze[3] reports twelve cases of acro-paresthesia, as he calls the affection, and makes an elaborate study of the symptomatology. He thinks the symptoms are all opposed to the theory of peripheral neuritis, but believes that the disease is somewhat analogous to neuralgia. He considers the etiology obscure, and regards manual labor as having but little influence. He admits that many cases occur at about the climacteric, but says that the influence of that period is wholly unknown. He states that he has found treatment not very efficacious; that drugs are of no use, except to relieve pain, when

[3] Deutsche Zeitschrift für Nervenheilkunde, 1893, iii, p. 300.

present; but that electricity, warm baths, and warm applications may do some good.

Friedmann[1] regards the affection as independent and individual, but harmless, notwithstanding its persistency. He also refers to the menstrual period in women as influencing the onset of the disease. He is disposed to ascribe the trouble to general anemia, with a weak circulation, and thinks that there is often some cardiac affection, usually a slight amount of fatty degeneration. He divides the affection into four classes: the acute and the chronic; a form in which the symptoms begin suddenly and are associated with vertigo (this variety is probably due to some brain-lesion); and a fourth class of cases, in which there is a tendency to rheumatic troubles. He is inclined to refer the trouble to two pathologic conditions: passive hyperemia of the extremities and irritation of the peripheral branches of the nerves. In treatment he recommends electricity, tonics, and cardiac stimulants.

Laquer[2] analyzes eighteen cases in women between thirty-five and forty, and recognizes the features as described by Schultze; but, contrary to that observer, regards the influence of hard work with the hands as being of great importance in an etiologic relation. He regards the affection as a neurosis due to exhaustion.

The observation of a considerable number of cases since 1884 has confirmed the views which I then expressed as to the pathology and etiology of the disease. There is probably in all cases of paresthesia some change in the blood-supply of the peripheral nerves. In those of an intermittent character there is only hyperemia; but in others in which the symptoms are constant, there is, no doubt, a slight but distinct inflammation of the terminal filaments of the peripheral nerves. A patient whose case I have already related[3] illustrates the influence of the menopause in causing paresthesia:

Mrs. Y., forty-one years old, was referred to me by Dr. Oliver P. Rex. Her menstruation had been regular until six months before, when there was a cessation for seven weeks, and then a uterine hemorrhage occurred. An extra-uterine pregnancy was diagnosticated, and at the end of three months celiotomy was performed and a fetus and both ovaries removed. The patient made a good recovery and got up at the end of three weeks. Soon after this she began to have flushes of heat several times a day. Three or four weeks later she had attacks of numbness in the right hand when she awoke from sleep. At first there was only numbness, but later there appeared a sense of prickling and pain, which would awaken her from sleep. In a few days both hands were affected, and they soon became numb all the time. The numbness was most intense in the afternoons, and especially in the distribution of the ulnar nerve. When the woman went to sleep the whole arm became numb and painful, and she was awakened by the sensation. Sleep was, therefore, almost impossible and she walked the floor most of the night. When I saw her this trouble had existed for five weeks; the temperature of the hands was normal, tactile sensation, localization, and appreciation of compass-points were unchanged; but the patient was awkward about sewing and the use of her fingers generally.

In this case the premature induction of the menopause by the removal of the ovaries brought on the vasomotor symptoms which belong to that condition when it comes on naturally, and the symptoms were more intense than those met with under ordinary circumstances. Complete relief was afforded by the administration of ergot.

Various writers have suggested different plans of treatment for this form of paresthesia. Putnam recommended strychnin, phosphorus, and potassium bromid, with the use of galvanism. Omerod found potassium bromid useful. Collins believes that there is no specific remedy, but regards prolonged rest, with restorative treatment, the most beneficial therapeutic measure. The use of the faradic current he considers helpful, but he believes a general tonic plan of treatment, with out-door life and change of occupation, of the most importance. In my paper to which I have referred, I stated that the treatment that I had found most useful was the administration of ergot, and that I had used this drug with the belief that the cause of the paresthesia was a hyperemia of the nerve-trunks or of the terminal filaments. As ergot is supposed to cause contraction of the arterioles, it seemed the proper remedy. I also suggested that in some cases there might be congestion of the cervical enlargement of the cord, from the fact that the numbness is often bilateral, and that the attack is most frequently induced by sleep. More extended experience has confirmed the belief in the utility of ergot in this disease, and I shall cite two illustrative cases:

Mrs. D., thirty-four years old, has always been healthy. Menstruation has always been scanty, and before marriage painful. She has been married twelve years and has had four children. She has had a slight attack of rheumatism, followed by pain in her left side, which becomes weak from overwork. Recently she has had great care and worry in nursing two sick children. Five or six months before coming under observation she began to have a sense of numbness in her shoulders, which extended to the epigastrium, and then appeared in the hands and feet, changing its location from one foot to the other during the day, but becoming

[1] Deutsche Zeitschrift für Nervenheilkunde, 1893, iv, p. 450.

[2] Neurologisches Centralblatt, March 15, 1893.

[3] "Remote Results of Removal of the Ovaries and Tubes," University Medical Magazine, December, 1891.

much worse at night. There is a continual sense of numbness of varying degree in the fingers and hands. It becomes painful in the early morning, but after use of the hands and arms for a time there is less intense prickling, and she is able to go on with her work. There is no anesthesia, and with the dynamometer the grasp of the right hand is 100, that of the left 90. There is no change in the temperature-sense. The patient was very anemic, and was ordered twenty drops of the tincture of ferric chlorid three times a day, and advised rest and good food. She followed this treatment for two weeks and then reported that she was not so well. She was looking better and was less anemic, but complained of an increase of the numbness in the hands, arms, and feet, and had some dizziness and precordial pain. She took iron in full doses for a month. At the end of that time the paresthesia was no better, if anything, worse; and she was then ordered gtts. xxx of the fluid extract of ergot, three times a day. In two weeks she reported that she was very much better, having taken the half-dram doses of ergot steadily. She was now ordered to return to the iron, and took this for two weeks, when she again reported that the numbness in her hands had increased. Ergot was once more prescribed, with immediate relief to the symptoms, and she took this remedy at intervals for some weeks. There was a return of the numbness several times, but it was always relieved by the administration of ergot.

Mrs. B., thirty-three years old, has two children, and has always enjoyed excellent health, with the exception of an attack of chorea, which lasted from the twelfth until the fifteenth year, since which time she has always been somewhat "nervous." She is a very healthy-looking woman, with bright color, and is in good flesh. The urine was found to have a specific gravity of 1018, to be slightly acid, and contained neither albumin nor sugar. She has had some dysmenorrhea since marriage, but menstruation has otherwise been regular and normal. About three months before coming under observation she began to have numbness in the left hand on rising in the morning. This soon extended to the right hand, and then became painful. The numbness and painful prickling soon extended to the shoulders. In a few days sleep became disturbed, and soon the numbness was so great that she would be awakened by it soon after falling asleep, so that for several weeks her rest was greatly broken. Within a few weeks the numbness extended to the feet and legs during sleep. There is no loss of sensation, and the patient is able to use the hands in sewing and in performing other acts. She was ordered a pill of ergotin, grs. ii, and the extract of cannabis indica, gr. ¼, three times a day. In three or four days she reported very marked relief from the numbness, and the dose of ergotin increased to grs. vi *ter in die*. In two weeks she stated that she was very much better, that the numbness had left all of the extremities except the left arm, and it was here very much less. She was then directed to withhold the ergotin and to take lithia-water freely. She remained free from the numbness for two weeks, when she had a sharp attack, chiefly affecting the fingers and hands. She was then ordered to renew the pills of ergotin and cannabis indica, and in a few days reported complete relief. She was still nervous, and was given a pill of iron valerianate, quinin, and strychnin, and has remained free from any numbness up to the last report that I have had of the case.

While ergot relieves very quickly the numbness and painful formication in these cases of paresthesia, it is always necessary to use additional means for the improvement of the general nutrition. Massage is of great value, and general faradization is also useful. Change of air, and tonic doses of iron, quinin, strychnin, usually effect a cure after the relief of the symptoms by ergot. There are cases of paresthesia which are due to lithemia, and these usually yield to appropriate anti-lithemic remedies.

ORIGINAL ADDRESS.

ADDRESS ON OBSTETRICS.[1]

BY E. E. MONTGOMERY, M.D.,

PROFESSOR OF CLINICAL GYNECOLOGY, JEFFERSON MEDICAL COLLEGE; GYNECOLOGIST TO JEFFERSON AND ST. JOSEPH'S HOSPITALS; OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL.

IT may seem at first thought the part of presumption for a surgeon to attempt the address upon obstetrics. But this may be condoned when we appreciate that obstetrics and the surgery of women have been so long associated in teaching—the one almost considered an outgrowth of the other—and that it has been customary in this Society to consider the discussion of gynecologic subjects as eminently proper in the obstetric address. We have still less hesitancy to conjoin the subjects, as we shall in this paper, when we appreciate that the nearer we approach the surgical standard of antisepsis and asepsis in every case of confinement the better are the chances of the patient and the less the danger of subsequent distressing sequelæ. We do not propose to attempt a *résumé* of the field of obstetrics or gynecology, but shall consider a few of the more important conditions from a surgical standpoint.

Symphysiotomy. The revival of this operation by the Italian surgeons almost threatens to again divide the obstetric world into the Symphyseans and Cesareans. We owe a debt of gratitude to Dr. R. P. Harris for the careful and painstaking manner in which he has presented the history and statistics of this and the subject of abdominal extraction of the fetus, by which our ability to save life has been enhanced. Like all new or revived procedures, symphysiotomy has been performed unnecessarily or in unsuitable cases, and, in consequence, the procedure is brought in some degree into discredit. Enough has been done to demonstrate that we have in this procedure an operation capable, within certain limitations, of decreasing the danger for both mother and child. It serves to bridge over the gap between forceps-delivery and Cesarean section, formerly considered as affording greater safety for the mother through embryotomy. The limit below which symphy-

[1] Read before the State Medical Society of Pennsylvania, May 16, 1894.

siotomy should not be performed has been fixed at 6.75 cm. (2.7 inches). This is also the maximum limit for generally successful craniotomy.

Some of the objections that have been raised against symphysiotomy are: (1) that it is a difficult and tedious operation; (2) a second operation is required to deliver the child; (3) the occurrence of injury to urethra or bladder; (4) the danger of sepsis. It cannot be denied that there is some basis for these objections, but the procedures we would substitute cannot be said to be free from disadvantage, and when we consider that through the procedure under discussion one individual is afforded an even chance for life, we may overlook its minor disadvantages. Indeed, we feel that we may now hail the day for which some of us have been so earnestly pleading, when craniotomy upon the living child may be considered as a relic of barbarism, and no longer a justifiable procedure.

If the surgeon may be permitted to suggest rules for the government of the obstetrician attempting to save the life of the unborn, it would be as follows: (1) careful examination should have been made of every patient prior to her coming into labor, in order to determine the size and condition of the pelvis; (2) when previous labors have demonstrated the inability of the patient to deliver herself at full term with safety to the fetus, and examination discloses this to have been due to a faulty condition of the pelvis, measures should be instituted to insure the most favorable termination of the approaching labor for the child, whether that be by the use of forceps, version, symphysiotomy, or the Cesarean section; (3) when the conjugate is above 9.4 cm. (3¾ inches) forceps should be employed or version should be practised; when between 9.3 cm. and 6.75 cm. (3¾ inches and 2.7 inches) symphysiotomy should be performed, followed, if necessary, by the use of forceps; when below 6.75 cm. Cesarean section should be the elective operation for both mother and child. It may be asserted that the patient will not consent to a cutting operation, preferring death to her offspring, but the physician should place himself firmly in the position that he has two lives in his hands, each of which is entitled to consideration, and if the mother declines a procedure that affords her a reasonable chance of restoration to life and health, and a chance for her offspring, such declination does not justify the physician in being not only accessory to the taking of human life, but its actual destroyer. If he is forced by this stand to give up his patient, he will at least have the satisfaction of feeling that he has stood up for the rights of a being unable to speak for itself.

When it can be demonstrated by the length of time the woman has been in labor, by the physical signs, and by the absence of the heart-sounds that the fetus is dead, that method of delivery should be adopted which will expose the woman to the least danger and discomfort. When the woman has been in labor for some time, and the uterus has been contused and injured to such a degree that its structure is likely to become gangrenous, the better plan of procedure will be a modification of the Porro operation. I say modification, for the reason that I do not think it wise in any such case to treat the stump externally if we can so arrange matters as to completely close the abdominal wound. This can be done by the entire or complete extirpation of the uterus, or the removal of the organ with the exception of a small portion of the cervix which projects into the vagina. In such cases the peritoneum should be closed over the stump, to exclude it entirely from the peritoneal cavity. Drainage may be secured by packing the cervix with iodoform-gauze, which may subsequently be removed through the vagina.

Placenta prævia. The one condition in which the future of the fetus should be ignored is placenta prævia. This is particularly true in the cases of central insertion of the placenta. Thus, when a patient begins to have hemorrhages as early as the fifth month, coming on suddenly without any warning, possibly while lying in bed, and becoming so severe as to endanger her life, with the knowledge that she may at any time die from an uncontrollable hemorrhage, and the improbability that the fetus will reach a viable age, there should be no question of the wisdom of evacuating the uterus, and thus afford the patient the best chance for life. In such cases the more rapidly the labor is induced the better it will be for the patient. We may, oftentimes, under the influence of an anesthetic, succeed in dilating the cervix until it will admit two fingers, and then by the Braxton-Hicks method perform podalic version and draw a leg of the child into the cervix and control the hemorrhage until the labor is completed.

Sepsis. The laity has become so well informed of the causes of diseased conditions that it has become a discredit to the obstetrician to have a case of sepsis develop in his practice. While even the most careful man may not be able to escape the development of such conditions, it must not be forgotten, however, that the infection takes place through some unguarded avenue, and the patient becomes the victim of a grave condition. This may manifest itself, of course, in a variety of ways, some of which are amenable to prompt measures, while others will be beyond control from their inception. Infection by the genital tract, as in other portions of the body, may involve the general system and affect the tissues in several different ways. One is by continuous and contiguous extension. Thus, inflammation may extend through the mucous membrane of the uterus to that of the tubes, and finally to the peritoneal cavity; or we may have the infection enter the system through the bloodvessels or the lymphatics. The manifestations of the disease vary greatly according to the method by which the infective agents gain entrance. The more rapid and more virulent form of disease is that in which it enters through the bloodvessels. The most difficult form to manage is that in which it has entered through the lymphatics, forming secondary abscesses in the lymphatic glands. Inflammation extending through the uterus and the ovaries is particularly destructive of the function of reproduction, but it is more self-limited as regards the individual than when the poison enters through other avenues. Thus, the infection and establishment of inflammation in the tubes lead to increased secretion, which coming in contact with the peritoneum sets up at once an inflammation that closes the abdominal end of the tubes, so that a sac is formed, including ovary, and resulting in a tubo-ovarian abscess. The disease becomes self-limited, and results in the formation of abscesses which are necessarily a source of peril to the life of the individual until relieved by operation. With

this knowledge of the progress and results of septic troubles, it is incumbent upon us early to be on our guard regarding the danger of such conditions.

The symptoms of sepsis are: Chill, fever, pain, tenderness, and offensive discharge. In every case of rigor, an elevation of temperature should not be considered as an indication of a beginning septic process, but it should certainly be a warning to lead us to investigate thoroughly as to its cause and watch carefully the subsequent progress of the case. Should the condition not yield promptly to suitable treatment, or should it be accompanied by an offensive discharge, we must not be content with anything less than a complete sterilization of the cavity of the uterus. This cannot be accomplished by mere irrigation with antiseptic solutions, for the uterine cavity is lined with débris, the surface only of which is affected by irrigation, while in the deeper portions germs continue to multiply and ptomaïns develop, the absorption of which causes the elevation of temperature. The proper plan of procedure would be the cureting of the cavity of the uterus with a sharp curet, subsequent irrigation successively with hydrogen dioxid, sublimate solution, and finally sterilized water, after which, in order to make sure of separation of the uterine walls and thorough drainage of the cavity, the uterus should be packed with a good-sized twist of iodoform-gauze. This serves several purposes. It affords drainage through its capillary action; it keeps the surfaces of the uterus apart; it stimulates increased discharges of serum and consequent depletion of the walls; and finally, by its presence as a foreign body, it stimulates uterine contractions, thus diminishing the facility with which the material can find entrance into the sinuses.

This plan of procedure, carried out sufficiently early, will prevent further extension, but when the disease has already extended and secondary foci have formed in the uterine sinuses, in the lymphatic glands, in the Fallopian tubes, or in the peritoneum, the operation will not be an entire success. In such cases it may be necessary to resort to more radical procedures. Should the temperature of the patient continue high and rigors occur, we should feel assured that secondary foci had already developed, and if examination failed to disclose disease in the tubes and ovaries, early section should be resorted to, in order to disclose definitely the condition of the uterine walls. Not infrequently we shall find that the uterine sinuses contain pus-collections, and in such cases the elevation of temperature is very marked and the condition of the patient is an extremely critical one. In such cases, by all means the best method of procedure is extirpation of the uterus. Exploratory section, at at least, should be made with a view of ascertaining, so far as possible, the condition of the uterine walls. Absence of any disease in the uterus should lead to exploration of the tubes and ovaries. If the latter organs are considerably enlarged, it would be well, after carefully packing about to protect the abdominal cavity, to puncture the ovary with a clean knife and ascertain the character of the fluid causing its distention. I have reported a case in which the ovaries were removed because they were quite large, and in which careful examination disclosed that there was no sign of disease in the uterus. The left ovary, the larger, was opened after its removal and found to contain a teaspoonful of foul, greenish pus. Although the patient had repeatedly a temperature reaching 106°, and one of 104° at the time of the operation, her temperature soon became normal and convalescence was uninterrupted.

The presence of masses of exudation in the pelvis, accompanied with tenderness and elevation of temperature, should be considered an absolute indication for resort to abdominal section. It is true that in some cases of this kind the exudation may be absorbed, and the patient slowly convalesce; but it will be found that the patient is crippled, and that adhesions have occurred between the ovaries and tubes, binding them down, oftentimes completely involving the tube and ovary, and producing a painful condition which leads to semi-invalidism.

Vaginal Hysterectomy. The rapidity has been unexampled with which this operation has been accepted by the general profession. The operation was introduced for the relief of patients suffering from carcinoma of the uterus. While its practice for this purpose is rarely questioned, the indications have been extended, so that the operation is now considered advisable in cases of fibroid tumor of small size in the wall of the uterus or within its cavity, giving rise to profuse bleeding, marked prolapse of the organ, and finally, in cases of sepsis when it is recognized that the disease involves the uterine walls as well as other pelvic structures. Some have gone so far as to claim that the uterus is a mere excrescence in every case in which it is necessary to resort to the removal of the ovaries and tubes. While we would not assent to this, we do believe there are many cases in which the inflammatory or suppurative processes involve the uterine walls and in which the patient would have a much better chance for recovery if the entire uterus were removed, and even when recovery from the operation has taken place, the patient has suffered and remained crippled as a result of the uterine inflammatory process.

Vaginal hysterectomy is an operation not difficult of performance in ordinary cases, and one in which the mortality is not great. I have had twenty-seven cases of vaginal hysterectomy, with two deaths, neither of which could be directly attributed to any fault in the operation. The first patient died from tetanus at the end of the fourteenth day; in the second case, a violent attack of catarrhal jaundice developed on the second day in a woman who had been subject to attacks of hepatic inflammation, and who died at the end of a week. In the second case there was intense jaundice, discoloration of the urine, absence of bile from the feces, exceedingly slow pulse, generally normal or sub-normal temperature, and finally delirium and coma.

During the past summer a homeopathist of Chicago gave wide circulation to what he claimed as a new method of hysterectomy, which was simple, safe, bloodless, entirely obviating the necessity of either clamp, cautery, or ligature—a major operation converted into a minor one by a simple process of easy dissection. This operation consisted, after cutting through the vagina, in pushing off the tissues from the structure of the uterus, and performing a practical enucleation of the organ. As the large uterine and ovarian vessels do not enter the uterus directly, but form anastomotic communication in either broad ligament, from which numerous small vessels are sent into the organ, you can readily see that by pushing off the tissues and tearing these

vessels, the ragged edges contract, close the orifices, and prevent hemorrhage. There are cases on record in which a midwife has torn away the entire uterus when inverted, supposing it to be the placenta, and the patient recovered. Investigation of the literature of the profession discloses that this operation is not a new one, but was suggested by Langenbeck as early as 1813.

The operation of enucleation, however, is a slower one. There is increased danger, particularly in cases of carcinoma of the body of the organ, of leaving a portion of the infected tissue, and I must individually confess to a certain amount of anxiety and fear as to the certainty of controlling the hemorrhage. As the clamps are applied the operation is a speedy one, and we have no fear that hemorrhage will subsequently occur. The same method of operation has been utilized in abdominal hysterectomy, whether the entire or only a portion of the uterus is removed.

Eastman has devised a saw-like knife with which, after the fundus is fixed, he proceeds to separate the tissues, tying the ovarian artery on either side, and then tearing off the tissues remaining, not even using a ligature for the uterine arteries. Whether we have the courage of Eastman, to tie only the ovarian arteries, and practically tear away the other vessels, the general principle remains accepted that in removal of the uterus through the abdomen, whether for growths or for malignant disease, either the entire organ, or all but that part of the cervix remaining within the grasp of the vagina, should be included. When a portion of the cervix is left behind, it should be dilated, its canal sterilized with the thermocautery or strong carbolic acid, and a rope of iodoform-gauze carried through it to afford drainage from the raw surface above it. The peritoneal flaps should then be closed with a continuous suture of fine silk, catgut, or kangaroo tendon.

The advantages of such a procedure over the old extra-peritoneal method are: 1. That we are enabled to close at once the external wound, thus greatly hastening the recovery of the patient. 2. The strong retraction of the stump and closure of the wound by a granulating process is avoided. 3. The danger of subsequent hernia through an abdominal wall, weakened by the placing and subsequent retraction of the stump, is greatly decreased. 4. The probability of sepsis is lessened.

CLINICAL MEMORANDA.

A CASE OF ACUTE DELIRIUM.

With some Considerations on its Pathologic Aspects.

By THOMAS P. PROUT, M.D.,
PATHOLOGIST AND SECOND ASSISTANT PHYSICIAN TO THE NEW JERSEY STATE HOSPITAL AT MORRIS PLAINS.

Authorities are at such variance as to the existence or non-existence of brain-lesions in acute delirious mania that I deem the following case of especial interest, presenting as it does both macroscopic and microscopic lesions of some import:

L. S., a colored farm-laborer, twenty-five years old, was admitted to the New Jersey State Hospital at Morris Plains, April 27, 1894, with the following history: The patient had always been regular in his habits and industrious. About one week before admission he suddenly manifested maniacal tendencies, and threatened his employer's life. The authorities immediately took him in custody, and after a sojourn of about one week in the county jail he was brought to this institution in restraint. The patient was so much exhausted that for a short while after admission he was very quiet; but he soon became maniacal, singing and shouting at the top of his voice, and pacing about the ward in an excited manner. He slept very little during his first night in the institution, and was considerably excited during the next day. He took a little food at dinner-time, and slept during the following night under the influence of paraldehyd. On the next morning he seemed very quiet, but listless, occasionally ejecting a quantity of greenish, frothy material from his stomach. Nausea subsided under the influence of small doses of calomel frequently repeated, and the man slept fairly well during the night. On the following day it was determined to feed him, as he had up to this time taken very little food, and he seemed to be fast losing ground; he was accordingly given a sufficient quantity of milk both morning and evening by means of the nasal catheter. During the afternoon he was noisy, but slept fairly well during the night.

On May 1st the man had slight fever in the morning. The tongue was dry. The patient was very quiet all day, and seemed on the whole slightly better. He took milk voluntarily, and manifested no gastric disturbance. His bowels were moved during the day. Nothing further of interest occurred till about 3 o'clock on the following morning, when the night-nurse sent me a report that the patient had suddenly become worse, and was apparently dying. Death occurred about twenty minutes afterward.

The following is abstracted from the autopsy records: The autopsy was made eight hours after death. The pia mater was engorged with blood, but not adherent to the brain-surface. The brain-mass, as a whole, was of greatly diminished consistence, and on section showed marked congestion, although very little blood exuded from the puncta vasculosa, which were very numerous. The softening seemed general, but was most marked in the frontal and parietal segments of the brain.

On laying open the circle of Willis three thrombi were found, one in the basilar artery, successfully occluding its caliber; this thrombus was formed apparently from a thrombotic shred which had been thrown into several folds by the blood-stream, and had received some recent additions in the way of dark clotted blood. The two thrombi in the middle cerebrals were much smaller, the one on the right side being the larger of the two, but neither successfully occluded the caliber of the vessel.

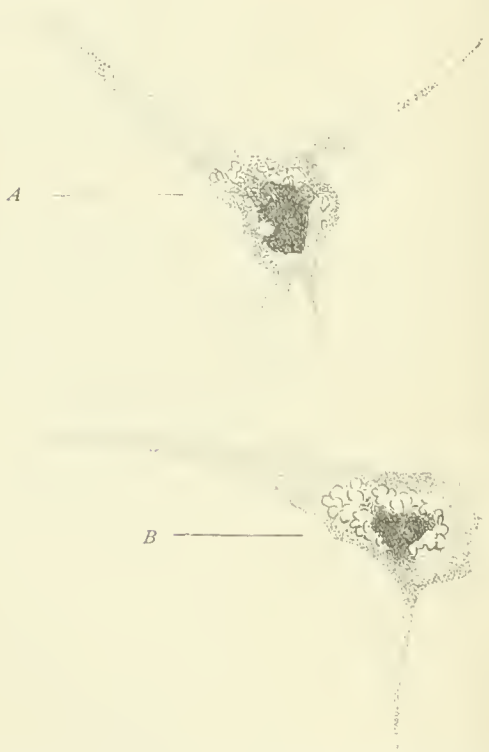
The longitudinal sinus contained an ante-mortem clot, which did not, however, occlude the caliber of the sinus. The heart contained a large thrombus in the right auricle, firmly attached to the tricuspid valve, and occupying about one-third of the space in the auricle; a smaller thrombus in the right ventricle, extending up through the pulmonary orifice; a similar clot in the left ventricle, extending up through the aortic orifice; and also one in the left auricle, firmly attached to the mitral valve. The stomach presented three ulcers, one along the lesser curvature, of very recent origin, midway be-

tween the pyloric and cardiac orifices, and two smaller ones near the pyloric orifice, each about the size of a dime. These were apparently the older.

This case is interesting from a pathologic standpoint, on account of the unusual lesions found to account for the symptoms and the patient's unlooked-for death. Considering the man's age and his previous healthy condition, it seems not improbable that his sudden manifestations of violence were coincident with the occurrence of partial thrombosis of the basilar artery, the mania being due to the serious disturbance in the cerebral circulation, and consequent impairment of nutrition in the ganglion-cells of the cortex. The circulation was still more seriously impaired when the thrombotic shreds in the middle cerebral vessels became thrown into folds and seriously narrowed the lumen of the vessels, and death was to have been expected as soon as the cerebral blood-supply became sufficiently limited by the gradually increasing obstruction to the vascular stream.

The microscopic appearances of the cortex were of interest, because they were unlike the conditions found in three cases of acute delirious mania examined previously, and all of which presented the same lesion.

FIG. 1.



A. Vacuolation of protoplasm of cell; nucleus hazy in outline (upper portion). *B*. Marked vacuolation of protoplasm of cell; nucleus small and hazy in outline. (Zeiss $\frac{1}{12}$ imm. obj., Abbe camera lucida.)

The protoplasm of the cell in the neighborhood of the nucleus was almost invariably vacuolated, the degree of vacuolation varying from two or three small, rounded, light areas to large clumps of these (Fig. 1), which in many instances seriously invaded the nucleus, and in a few almost entirely replaced it. (Figs. 2 and 3.) The changes in the nucleus were quite extensive,

FIG. 2.

Vacuolation of protoplasm of cell and nucleus. (Zeiss $\frac{1}{12}$ imm. obj., Abbe camera lucida.)

but not general; when present they were quite well marked. In very many instances the nucleus was apparently swollen; in these cases it was always very irregular in outline, but the edges were sharply defined. (Fig. 4.) In other instances portions of the circumference of the nucleus were sharply defined, while other portions were very hazy, shading off gradually into the protoplasm of the cell (Fig. 1, B). In many other instances the nucleus was seriously encroached upon by the morbid process in the protoplasm (Fig. 2); in a few instances being occupied by one or two vacuoles, while in a few others it seemed almost entirely destroyed (Fig. 3).

The microscopic appearances are of especial interest when considered in connection with three other cases of acute delirium that have come to autopsy in this institution in the past year and a half, because of the entirely different nature of the predominating microscopic lesion. In these latter cases pigmentary degeneration of the ganglion-cells was the most prominent feature, being widely distributed and extremely well marked. In the case under consideration there was not the slightest trace of pigmentary degeneration anywhere in the cortex; in fact, the normal deposit of pigment seemed absent from most of the cells.

In considering the apparent variability in the pathologic phenomena presented by these cases, I must con-

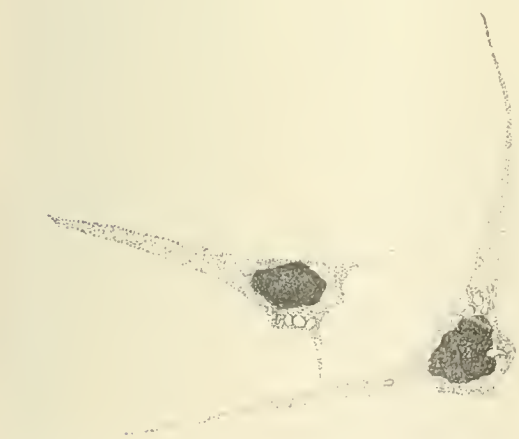
fess that the cause for such variability is not entirely apparent; nevertheless we have to consider the fact

Fig. 3.

Nucleus almost entirely replaced by vacuoles. (Zeiss $\frac{1}{12}$ imm. obj., Abbe camera lucida.)

that while the case was undoubtedly one of acute delirium, the nature of the delirium differed somewhat

Fig. 4.



Enlarged and irregular nuclei. (Zeiss $\frac{1}{12}$ imm. obj., Abbe camera lucida.)

from that of cases ordinarily seen, in that it showed a marked disposition to be transient. We must also bear in mind the lesions existing in the vessels at the base of the brain as having a modifying influence on both symptoms and pathology, no such factor figuring in any of the previous cases.

In connection with this case the work of Dr. H. C. Hodge, of the Clark University, is of exceeding interest. In his study of the changes in nerve-cells after functional activity he demonstrated vacuolation of considerable extent as occurring in the nerve-cell after normal fatigue, together with considerable shrinking of the nucleus. In this case there can be little doubt of the existence of extreme fatigue, as the patient was inclined to violence, and often made night and day hideous to those with whom he was associated. Bearing this in mind, the question of the pathologic significance of the phenomena under consideration is an interesting one.

Are vacuoles in nerve-cells of any pathologic import, or is their presence simply an indication of the expenditure of nervous energy? As a partial answer to this question we should bear in mind the occurrence of the most extreme degrees of vacuolation of nucleus and cell-body in primary and terminal dementia, forms of insanity uncharacterized by mental or physical activity of any description. The same might be said to a lesser degree of the different forms of melancholia. On the other hand, the occurrence of vacuolation in epileptic and some other forms of insanity is well known, and according to Hodge it occurs also as a direct result of physiologic fatigue.

In mental disease the nucleus is most often the seat of the morbid process, while in physiologic fatigue the protoplasm of the cell-body is chiefly affected. The forms of vacuolation also differ widely. In the conditions studied by Hodge the vacuoles seemed evenly distributed through the nerve-cell, while in the case under consideration the vacuoles were grouped together in masses, in the neighborhood of the nucleus, and in some instances involved the nucleus also. It would seem, therefore, that we may consider cellular vacuolation, aside from any physiologic process, as a pathologic factor in insanity of some importance.

In conclusion, the proposition may be made that interference with the cerebral circulation may give rise to maniacal outbursts as a direct result of nutritional disturbances in the ganglion-cells of the cortex. Nutritional disturbance is manifested, first, in the brain, by the marked diminution in the consistence of the cerebral mass, and, second, in the ganglion-cells, by vacuolation of the protoplasm of the cell-body, and in fewer instances of the nucleus also.

A CASE OF GENERAL TUBERCULOUS LYMPHADENITIS WITHOUT INVOLVEMEMT OF OTHER ORGANS.

By D. J. MILTON MILLER, M.D.,
visiting physician to the episcopal hospital, philadelphia.

W. M., a teamster, twenty-two years old, was admitted to the Episcopal Hospital, February 5, 1894. There was no family history worthy of note, nor had the man any previous illness beyond an attack of measles in childhood. His present illness began three months before, when he first noted swelling of the cervical glands (he insisted that they were not swollen before that time).

Four weeks before admission he was attacked with pain in the back and limbs, accompanied by great weakness. He had spells in which he would "tremble all over" and feel chilly, but there were no actual chills. He perspired profusely and continuously, by day as well as by night; but he did not think he had fever, nor had he any cough.

On admission he was noted to be a very thin man, who had evidently lost flesh recently (five pounds in the preceding few weeks, he said). The cheeks were flushed; but the surface was cool to the touch, and the thermometer registered 95° F. in the mouth; the pulse was 120; the respirations 18. The whole surface was bathed with perspiration, which, on the forehead, stood out in large drops. The epidermis of the palmar and plantar surfaces was sodden and macerated, and the skin of the trunk (chest and back) was covered with a profuse vesico-papular eruption. The lymph-glands of the neck were very much enlarged. This condition was particularly marked on the left side, where the glands formed large masses, two of them the size of a hen's egg, under the inferior maxilla and anterior to the sterno-mastoid muscle. The same description applies to the right side, though the masses were smaller, not larger than a walnut. The posterior cervical, the axillary, and the inguinal glands were also slightly enlarged.

The tongue was coated; anorexia existed; the bowels were regular; there was much pain in the abdomen about the umbilicus; the area of hepatic dulness was not increased; the spleen was slightly enlarged; the thoracic organs were apparently healthy. There was a peculiar tremor of the muscles, very much like a fibrillary contraction; this persisted throughout the course of the case. The only symptoms the patient complained of were profound weakness and the constant sweating.

The further history of the case was one of progressive asthenia. Two remarkable features characterized the case throughout: profuse and constant sweating and a persistently low temperature. There were but few occasions during the seven weeks' residence in the hospital on which the whole surface was not bedewed with perspiration, and it is notable that, on the few occasions on which this was absent, the temperature rose to the normal or above. The sweat not only saturated the body and bed linen, but it induced an extensive eczema, which, as the case progressed, became pustular, so that during the last two weeks of life large crops of painful furuncles appeared, and, in addition, the epidermis over the hands and feet separated in large, sodden masses; while on the trunk a widespread desquamation took place. As a result (probably of this constant surface-evaporation) the temperature, except for a period of nine days, remained persistently and almost constantly below normal. During the first eleven days it only reached 98.5° twice. For the next nine days it fluctuated between 97° and 99°, only reaching the latter point four times. During the following twenty days it varied considerably, but it was almost always subnormal; its average range being from 96° to 97°, and only reaching or exceeding 98.5° fourteen times; on one occasion, when atropin (gr. $\frac{1}{200}$ t. d.) had been ordered the day previously, it rose to 102.2°. As the end approached, during the last nine days of life, the temperature ranged between 94° and 96°, and was below 95° eleven times; on four occasions falling to 94°. The thermometric observations were made every four hours. From time to time there was delirium, mostly of a mild character.

Shortly after admission the enlarged glands on the right side began to soften, and on the 27th of February a few drams of pus were removed by incision. Examination of this failed to reveal tubercle-bacilli.

Three different blood-counts were made by Dr. Joseph McFarland, but were very unsatisfactory, because of the difficulty in drawing sufficient blood. The first count gave 1,024,000 red corpuscles; the second, 875,000 red corpuscles; the third, 890,000 red corpuscles. The hemoglobin was estimated at 65 per cent. The number of colorless corpuscles was not estimated. The urine contained neither albumin nor sugar.

There was never any diarrhea or cough, and the examination of the chest was always negative. The patient was given a stimulant and tonic treatment. Syrup of hydriodic acid was administered during the whole course of the disease, but with no other than a tonic effect. For the night-sweats, atropin, gr. $\frac{1}{200}$ t. d., and in larger doses of gr. $\frac{1}{60}$, was the most effectual remedy. Camphoric acid, in doses of from fifteen to thirty grains once daily, made but little impression. Following Ringer's suggestion, pilocarpin, in doses of gr. $\frac{1}{30}$ was tried, but without the slightest result.

On the 25th of March death occurred rather suddenly, but it was momentarily expected, as the man had been growing gradually weaker.

At the autopsy (made by Dr. C. H. Frazier, the resident physician), although a careful search was made, all the viscera seemed healthy; for this reason a microscopic examination was not thought necessary. The spleen was slightly enlarged. The cervical glands were so clearly caseous and tuberculous that no further examination was made of them. The bronchial glands were enlarged, caseous and tuberculous. The mesenteric glands were also abnormal; they were enlarged, and on section showed tubercles and caseous deposits. The same, except that there was no evident tuberculosis and caseation present, may be said of the inguinal glands.

Dr. Joseph McFarland, pathologist to the hospital, to whom some of the glands were sent for examination, has given me the following report: "The bronchial gland is so obviously tuberculous, caseous, and calcareous that a microscopic examination was unnecessary. Its appearance leads me to believe that its lesion is one of long standing. Calcification of tuberculous deposits usually indicates chronicity, so that it is natural to infer that the disease of the bronchial glands in this case was one of the oldest lesions if not the primary one. The inguinal gland is also tuberculous, but presents a miliary tuberculosis of mild grade. The naked eye detects nothing, and the microscope alone reveals the presence of small, partly broken-down tubercles. I think the invasion a recent one, for the reason that the tubercles are few, and that each represents a rather rapid destructive coagulation-necrosis, which causes a granular caseation without giant-cell formation. Careful search was made for the tubercle-bacillus, but it was not found. This was probably due to the poor preservation of the specimens (they were kept for some time in weak alcohol), and not to the absence of the organisms. From

the microscopic appearance I have no hesitation in pronouncing the case one of tuberculosis."

General tuberculosis of the lymph-glands, without involvement of the other organ, is a very rare condition. In a very hasty and superficial review of the literature I have succeeded in finding no cases. Dr. Osler, however, in his *Principles and Practice of Medicine*, speaks of two cases which, in the main, resemble the one here described.

The almost constant subnormal temperature in this case is remarkable, but can be accounted for by the ever-present sweating, which kept the patient in a continuous bath. The skin was always extremely cold to the touch, and the patient was ever in a tremor. It would be interesting to know the cause of the almost uninterrupted sweating. It has been suggested that it was due to pressure on the cervical sympathetics, but it is difficult to believe that pressure existed to the same degree on both sides, and even if it did, it would hardly have caused universal sweating. The most plausible explanation, it seems to me, is that it was brought about by the same agencies that cause sweating in pulmonary tuberculosis, pyemia, and septic processes generally. But as we do not know what those agencies are, or, granting that we do, the exact manner in which they act, and as physiologists are not even agreed as to the causation of perspiration in the healthy, it would seem but a useless speculation to attempt to account for it in this case.

Thanks are due to Dr. Chas. H. Frazier, the resident physician in charge of the ward, for the notes of this case.

INDIGO CALCULUS FROM THE KIDNEY.[1]

By W. S. FORBES, M.D.,
of Philadelphia;
Professor of Anatomy in Jefferson Medical College, and Clinical Surgeon to Jefferson Medical College Hospital.

This specimen was found, *post mortem*, in the pelvis of the left kidney of a man who committed suicide in February, 1892, by turning the gas on in his room. The man was twenty-seven years old, about five feet nine inches in height, and weighed 150 pounds.

The examination revealed rigor mortis to be well marked. The peritoneum, the pleura, and the pericardium were normal. The heart was slightly hypertrophied, but its valves were normal. Both lungs were intensely congested and black in color, and did not turn red on exposure to air. They were not edematous. The peribronchial glands were intensely calcareous, and slightly larger than normal. The spleen was normal. The bladder was normal and was partially distended with urine, which on examination was found free from albumin, sugar, casts, pus, and blood. This case well illustrates the tolerance sometimes displayed by the kidney to the presence of even large calculi, for upon inquiry of the family of the subject from which the specimen was obtained, no history of pain or other symptom suggestive of the presence of the foreign body could be obtained. The right kidney was slightly movable in the perinephric fat, but was otherwise normal. The left kidney was surrounded by a thick fibrous mass, involving the entire perinephric fat. This inflammatory deposit also involved the blood-vessels passing to and from the kidney. The renal vein was much constricted in passing through the inflammatory mass. The ureter was bound by fibrous bands that slightly compressed it. An incision into the kidney revealed a calculus occupying the pelvis and one calix.

Professor W. M. L. Coplin, of Jefferson Medical College, made the post-mortem examination and handed me the kidney, with the calculus *in situ*. The specimen, of which an actual representation is here given, weighs 147 grains; its greatest thickness, fore and aft, is $\frac{19}{32}$ of an inch. It measures from A to B 1⅛ inch, and from C to D 1½ inch.

The dark-brown color caused me to think that it was formed of indigo, and drawing it across white paper it left a rough, blue mark, so that I was further impressed that it was perhaps indigo.

Ord, in his most excellent little work on the *Influence of Colloids upon Crystalline Form and Cohesion in Urinary and Other Calculi*, London, 1879, p. 144, has described at length what he believed to be the only specimen of indigo calculus in man that had hitherto been published. His specimen was a flat, hard cake, of the shape and size of a fruit-lozenge, and weighed forty grains; it was partly of a dark-brown color, three-fourths of its surface presenting a blue-black color; it was granular and without polish, and when drawn across white paper left a rough, blue mark.

The stone herewith presented reminded me so forcibly of Ord's indigo calculus that I determined to have it subjected to the same accurate test to which he subjected his specimen. The result was almost identical with Ord's. The dust of the stone was placed on platinum foil, and on applying heat the vapor emitted was collected on a glass slide, a drop of glycerin was added, and on comparing the specimen thus obtained with a preparation made in the same way with commercial indigo the appearances were identical. In both cases there were abundant blue prisms mixed with blue granules. The prisms were oblong, with pointed ends, and occasionally truncated.

The color-test was exactly the same in both specimens (Ord's and my own). Sulphuric acid dissolved the powder first into a brownish and then into a muddy-blue solution, which, after dilution with water and filtration, yielded a clear, blue fluid. This fluid gave in the spec-

[1] Read by title before the American Surgical Association at Washington, May 30, 1894.

troscope a marked band of yellow, without stopping the blue or red rays. The sooty odor on the application of heat was most decided.[1] The specimen may be seen in the Museum of Jefferson Medical College.

1724 WALNUT STREET.

A CASE OF ACCIDENTAL HEMORRHAGE.

BY EDWARD T. ABRAMS, M.D.,
OF DOLLAR BAY, MICH.

THE following case is reported with the hope that it may prove of interest to general practitioners that have not the advantage of being able to call in a specialist, but who must act upon their own responsibility and with their own knowledge.

In February last I was called to deliver Mrs. T., thirty-four years old, a quintipara. The previous labors had been normal throughout, and on my arrival in this particular one, things were progressing nicely. The pulse was strong, regular, and about 78. Labor-pains were strong and regular.

As it looked as if some time would elapse before labor would be completed, I lay down in the same room.

After a time I was startled to hear the woman say that she was feeling faint. I sprang to her side and found her pulseless and in a state of collapse. The pains had entirely ceased; the uterus seemed enormously distended and boggy. The face was pinched and pale—in fact the woman presented a typical picture of post-partum hemorrhage. A hasty vaginal examination showed the os to be fully dilated and the membranes intact, but negative as far as hemorrhage was concerned. I gave the woman a hypodermatic injection of whiskey and ergotin, and shortly had the satisfaction of feeling the pulse again at the wrist, though exceedingly rapid, weak, and irregular.

After waiting for some little time, with the hope that she would rally, and the condition of things not materially changing, I ruptured the membranes, applied the forceps, and delivered a fine male child; then a gush of blood followed, together with clots sufficient to fill a good-sized basin. By gently kneading the uterus it contracted well and gave no further trouble. Both mother and child were saved in this case. I believe, by the prompt stimulation and the complete, immediate emptying of the uterus.

WIDESPREAD PARALYSIS FOLLOWING DIPHTHERIA.

BY E. W. PRESSLY, M.D.,
OF CLOVER, S. C.

CARRIE B., aged eight years, was attacked by diphtheria during the first week of February. The attack was rather more severe than the average during the epidemic. The drum of the left ear was perforated, and at times fluids after being swallowed would escape through the ear. During the early portion of the convalescence paralysis of the muscles of the soft palate made its appearance, and fluids regurgitated through the nose on swallowing.

The paralysis next invaded the ocular muscles, giving rise to strabismus. The sphincter muscles of the iris became paralyzed, and the pupils enormously dilated. Diplopia was also complained of. In a short time the paralysis had involved both arms and legs, and the little girl was unable to turn in bed. The knee-jerks were entirely absent, and the surface of the skin not normally sensitive to touch.

Gradually, under treatment, the paralysis disappeared, and now there only remains a slight difficulty in the articulation of certain sounds.

The treatment consisted, during the attack of diphtheria, in the use of large amounts of tincture of ferric chlorid and whiskey, together with the use of antiseptic applications to the throat.

For the paralytic trouble I used strychnin, general friction of the entire body, bathing, and rolling in the open air in a child's carriage.

NEW DEVICE.

ILLUMINATION AND EXAMINATION OF THE ANTERIOR AND POSTERIOR NASAL CAVITIES.

BY D. BRADEN KYLE, M.D.,
OF PHILADELPHIA;
LARYNGOLOGIST TO ST. AGNES' HOSPITAL, INSTRUCTOR IN CLINICAL MICROSCOPY, AND ASSISTANT DEMONSTRATOR OF PATHOLOGY IN JEFFERSON MEDICAL COLLEGE.

THE method usually resorted to in the examination of the nasal cavities consists in the use of reflected light, which is projected into the cavity, as in the anterior cavities; or by means of reflected light and the rhinoscope, a view of the structures of the cavity is obtained, as in the post-nasal space. In order to obtain a clear definition of a body, the light should be at a point beyond the object to be examined and the position occupied by the observer. This is especially true of the various cavities. If a light then be placed within the post-nasal space a good view can be obtained through the anterior cavities, not only of the structures therein contained, but also largely of the naso-pharynx. With this end in view I have employed the following device, of which, so far as I am aware, the idea is original, at least in its application to nasal examinations and in the controlling of the heat by means of the aluminum cap. I am indebted to Mr. W. L. Turner, of Charles Lentz & Sons, for valuable assistance in the construction and perfection of this apparatus. A little incandescent light of four-voltage power is placed on the end of two light, insulated copper wires constructed the same as a cautery-wire. (See figure.) An objection was found in the inconvenience caused by the heat produced by the current and reflected from the lamp. To obviate this it was found, after testing many materials, that an aluminum-

[1] I am indebted to Prof. J. W. Holland, Professor of Chemistry in Jefferson Medical College, for the foregoing analysis.

cap could be used continuously for at least half a minute without any inconvenience; but by interrupting the current it can be used as long as desired. This cap has an opening to allow the escape of the rays of light, and also acts as reflector. The cap is so arranged that the aperture can be turned in any direction desired, so as to enable the observer to directly illuminate any part to be examined. The light is placed in position with the same movement as is used in introducing the rhinoscope, and when directly behind the arches the patient closes the mouth, holding the instrument firmly between the teeth. I have passed the instrument in a number of cases in which the fauces were extremely sensitive, and I find that if it is passed in the manner described no difficulty in retaining the instrument is experienced. The observer, then, with the aid of the nasal speculum, can obtain a perfect view of the parts. The light can be turned on and off at will. This method will also, after a little practice, largely enable the observer to determine the condition of the accessory cavities and parts, especially the antrum of Highmore. The connecting wire will fit any of the many handles now furnished with the equally many batteries. The battery used with this light is the Edco storage-battery of sufficient power to light a six-volt lamp. The whole outfit weighs less than twenty pounds.

1632 Chestnut Street.

MEDICAL PROGRESS.

Hydatid of the Brain.—Hawkes (*Australian Medical Journal*, vol. xvi, No. 4, p. 199) has reported the case of a boy, six and a half years old, who a week before coming under observation had a convulsion, in which the body became stiff and the face pale, but without cry or biting of the tongue. On inquiry it was learned that the child had had attacks of vomiting at intervals of one or two weeks during the previous four months; his mental condition had become dull; he was less inclined to play than formerly, preferring to lie down and sleep during the day. He had for two weeks complained of pain in the right frontal region, and during this time the right eyelid had been observed to droop and the gait to be a little unsteady. The child had gained flesh. The water-supply of the family was taken from a creek. The boy was well nourished and without external evidence of disease. Vision with the right eye was impaired and the pupil was dilated and fixed. The left eye, which turned inward, was normal. On ophthalmoscopic examination the retina of the left eye was seen to be of a bright-pink color, that of the right bright-red; the vessels were plainly seen. There was no tenderness on percussion of any part of the skull, but the child frequently put his hand to the right side of the forehead. There was general paresis of the muscles of the extremities, the grasp being weakened equally on both sides. A diagnosis of tumor of the brain was made, but an opinion as to the location was not ventured. The condition of the child underwent little change for two weeks, when he became unconscious; the temperature rose to 102.5°; there was complete flaccidity of the extremities, and there was no response to the hardest pinch; both pupils were widely dilated, and the corneal reflex could not be elicited. This condition continued for thirty hours, when the child showed signs of returning consciousness. Improvement gradually took place, and in the course of two weeks the boy was able to answer questions and recognize voices. At this time there was complete amaurosis and both pupils were dilated, particularly the right; ptosis of the right lid was not so marked as it had been; the sense of smell was completely lost; taste was impaired. The child was unable to stand without support; when in the erect position his head inclined forward and toward the right shoulder, and the whole body had a tendency to fall toward the right side. Sensation was not deranged. The pupils were widely dilated when the child was awake, but contracted when he was asleep. Two days later there was slight paralysis of the right side of the face, only noticeable at times; the tip of the tongue deviated to the right and there was some difficulty in swallowing. The probability of the existence of an hydatid growth implicating the motor area in the right cerebral hemisphere, as well as the right hemisphere of the cerebellum, led to the consideration of operative interference, but upon consultation this was deferred. The child died on the day fixed for trephining the cranium over the ascending parietal convolution at the junction of its middle and inferior thirds. Upon post-mortem examination a large hydatid cyst was found in the right cerebral hemisphere, extending from the cuneate lobe to the fissure of Rolando; the bones of the skull were thinned; the dura mater was congested, and there was a large blood-clot in the torcular Herophili, extending into the lateral sinus. The cyst presented in the longitudinal fissure through an opening about the size of a five-dollar gold piece.

Congenital Hydrocele of the Neck Cured by Drainage and Compression.—Dickinson (*British Medical Journal*, No. 1741, p. 1018) has reported the case of a healthy, intelligent-looking male child, three years old, that from birth presented a swelling in the lower part of the neck, in a vertical line with the left ear. The growth had gradually and progressively increased in size, and, following a slight blow, had become inflamed and threatened to suppurate; the inflammation, however, yielded to hot applications. The mass appeared as a soft, white, fluctuating swelling, translucent and pearly, owing to the thinness of its walls over the posterior half, having no discernible veins running over it, and becoming alternately tense and soft during crying and coughing. It extended from the sternal extremity of the left clavicle in front to the middle line behind, and quite filled up the sulcus between the neck and the shoulder, looking like a swimming-collar and overhanging the clavicle in front. A trocar and canula were passed into the cyst at its posterior and thinner part, and about eight ounces of dark greenish-brown, highly albuminous fluid, resembling bile-stained urine, escaped, with little or no force, the child breathing tranquilly at the time. A small incision, sufficient to allow of the introduction of the little finger, was made in the position of the puncture, and through this the cavity was explored. The sterno-mastoid muscle in the front wall of the cyst felt thin and atrophied; the carotid artery, lying by the trachea, and the subclavian, passing over the left lung, felt quite hard and clear, apparently having no covering and lying free in the cyst. No constriction or obstacle prevented the

finger from following the arteries downward behind the sternum to the arch of the aorta, which was felt pulsating vigorously, and as far as could be discerned was quite bare. The child at this stage showed signs of shock, turning pale and the respiration ceasing. After two efforts at artificial respiration, natural breathing was resumed. No further attempt at exploration was made, but a second small incision was made in the cyst-wall about two inches in front of the first and one inch behind the posterior border of the sterno-mastoid muscle. A piece of thin drainage-tube, passed in at one opening and out at the other, was found to be too rigid, crumpling up the intervening wall. A seton, consisting of five or six strands of fishing-gut, was therefore introduced and the ends tied together. A good pad of absorbent gauze was bandaged firmly over the site of the collapsed cyst. The wound was dressed on alternate days for thirteen days. At the earlier dressings a considerable quantity of blood-stained serum escaped and soaked the dressings, but the openings drained well, and not more than three-fourths of an ounce was ever found pent up. At the later dressings the character of the discharge became altered to a muco-purulent fluid and the temperature began to rise, the general health at the same time suffering somewhat. The seton cut its way out, and the wound continued to discharge more or less freely until five weeks after the operation, when it had healed and there was no appearance of any swelling or recurrence. The child rapidly regained its health.

THERAPEUTIC NOTES.

Potassium Iodid for Prostatic Hypertrophy.—DAVY (*British Medical Journal*, No. 1750, p. 68) reports a troublesome case of hypertrophy of the prostate, in which catheterization was almost impossible, and the patient's sufferings were so great as to require morphin for their relief. When a catheter could not be passed at all, the involuntary straining efforts to pass a few drops of urine were most distressing, the patient being bathed in perspiration and groaning with agony. For the relief of this condition potassium iodid was prescribed in the form of suppositories, each containing ten grains, one to be introduced into the rectum every night. In the course of some time the prostate became somewhat diminished in size, with corresponding relief from the distressing symptoms. Although a catheter could not entirely be dispensed with, the man was for the most part able to pass a fairly good stream of urine. It is recommended that the line of treatment pursued in this case be at least given a trial in similar cases before proceeding to measures of graver moment.

The Danger from Antipyrin, Antifebrin, and Phenacetin.—As the result of an inquiry conducted during the past year as to the frequency and importance of the ill-effects following the use of the three chief antipyretic agents, phenazone (antipyrin), acetanilid (antifebrin), and phenacetin, the Therapeutic Committee of the British Medical Association has found that the statements concerning these effects have been considerably exaggerated, most of all so in the case of antipyrin and phenacetin. The ill-effects observed, when not obviously due to idiosyncrasy, have in the majority of cases been the direct result of injudicious or excessive dosage. This has especially been the case with antifebrin, with which drug the ill-effects have been the most frequent and most serious. The dosage employed by no fewer than three-fourths of observers (from four to ten grains) has been habitually excessive, the proper dose of this drug being from one to four grains.

Ortho-chlorphenol and Para chlorphenol in the Treatment of Tuberculous and Other Affections of the Upper Air-Passages.—SIMANOWSKY (*Therapeutische Monatshefte*, viii Jahrg., H. 7, p. 329) has employed ortho-chlorphenol and para-chlorphenol in the treatment of tuberculous processes of the upper air-passages and in hyperplastic conditions and chronic swellings of the mucous membrane, using 5 per cent., 10 per cent., and 20 per cent. solutions in glycerin, or pure melted para-chlorphenol. The affected areas are either painted by means of a brush or a cotton swab, or the solution is injected by means of a laryngeal syringe. The application is for a short time followed by burning and pain, so that in the case of sensitive individuals the treatment may well be preceded by an application of a 10 per cent. solution of cocain hydrochlorate.

Chloral Hydrate for Hemoptysis.—Having in view the reduction of the pressure in the pulmonary circulation, PAL (*Centralbl. für die gesammte Therapie*, 1894, H. 7, p. 385) employed chloral hydrate in doses of from 15 to 37.5 grains by enema in the treatment of the hemoptysis of pulmonary tuberculosis, selecting young adults with healthy hearts. In some cases the hemorrhage would cease or diminish in from half to three-quarters of an hour, sometimes recurring after a varying interval. In a number of instances the administration of the drug was repeated, sometimes in a prophylactic way even after the hemorrhage had ceased. Morphin and codein may be expected to act with correspondingly good results, and morphin has the additional advantage of subduing cough.

The Use of Spartein as an Adjunct to Chloroform-anesthesia.—At a recent meeting of the Paris Society of Biology, LANGLOIS and MAURANGE (*Gazette Médicale de Paris*, 1894, No. 28, p. 331) stated that, governed by the influence of spartein in regulating the action of the heart and diminishing the excitability of the pneumogastric nerve, they were led to employ this drug to avoid the cardiac depression that sometimes manifests itself in the course of chloroform-inhalation. Their experience included, in addition to experiments upon animals, 120 observations upon man, sometimes in the presence of cardiac disease, sometimes when the operation was protracted. Their mode of procedure consisted in the injection of from gr. ss to gr. $\frac{3}{4}$ of spartein together with gr. $\frac{1}{3}$ of morphin fifteen minutes before beginning the chloroform-inhalation.

For Broncho-Pneumonia. SUTLIFF (*Occidental Medical Times*, vol. viii, No. 7, p. 398) recommends the administration of tincture of veratrum viride in small, frequently-repeated doses. Young nursing infants may have a fraction of a minim, and older children more, every two or three hours. Under this plan of treatment the pulse-frequency is reduced, the respiratory acceleration diminished, and the whole aspect of the case changed for the better.

THE CHILDREN OF THE STATE IN ENGLAND.

THE *British Medical Journal* has lately presented a series of articles setting forth the condition of the orphan-asylums and schools for destitute children in Great Britain. As a result of this exposition the public conscience has been so quickened that a deputation of two hundred prominent persons recently waited on the President of the Local Government Board, asking that an inquiry be instituted as to a better method of caring for the children of the State. A full report of this conference appears in the *British Medical Journal* for July 28, 1894, p. 211.

In looking over this the American physician is surprised to find that the orphan-asylums and "barrack-schools," as they are called, supported by the Local Government Board are practically prisons in which the children are kept from the world and from which the inquiring public is entirely excluded. It appears that the President of the Local Government Board confessed himself powerless to open the doors of these bastiles even in a single instance. This state of affairs is only approached by the condition of some of our city prisons.

Under these circumstances it is evident that all sorts of abuses are encouraged. The persistent criticism of scientific sociologists, the clamor of the laboring-classes and their powerful journals, the multiplied inspection and over-inspection by boards have driven out many of the scandulous abuses of twenty years ago; but there remain the inherent faults of the institutional system.

The destitute children of England are collected together in great barracks, from 200 to 1400 in each. They are fed, washed, and slept by machinery, at an almost incredibly small expense, but they grow into a physical maturity without a knowledge of the most ordinary conventions of life. They have never been in a home, and therefore they do not know what a home is, and they make mistakes that would be laughable were they not so significant. They are unfamiliar with the requirements of family, neighborhood, and business life. Of human affection, of kindness, of charity, of devotion, of hope, of ambition, of self-denial, and of brotherly love they know nothing. They have no moral or social development and training to prepare them for life in the world, and when they go out for themselves they are prepared for no career, and no avenues are open to them except those of crime and vice.

But even this is not the only indictment of the institutional system. Every child should be sent out sound and healthy, but these children are sent out with defective eyes and ears, with all sorts of skin-diseases, with imperfect and impaired, and even diseased, respiratory apparatus, and, again, with all those diseases and defects that follow the acute infectious diseases even under the most favorable circumstances. Defective vision, defective hearing, and consequent dull and undeveloped mental faculties, with lack of exercise and diminished vital force, form the heritage of those who survive the recurring epidemics of diarrhea, eruptive diseases, typhoid fever, diphtheria, and ophthalmia.

The death-rate has been and continous to be appalling. The crippled, bow-legged, rachitic, humpbacked, and scrofulous are more than twice as numerous among them as among the lowest independent poor. The average physical development is of the lowest grade.

The Charity Organization Society and the British Medical Association have collected information which the officials of the Local Government Board have not found time to investigate and have refused to publish. These documents have been published elsewhere. Nearly all the teachers and attendants in these institutions must, according to the rules of the Board, be unmarried. What a cruelty to practise on the children of the State, that they must be

cared for by old maids and bachelors, or those who do not have the softening influences and culture of a son or daughter! No wonder that 53 per cent. of the barracks-brought-up girls are reported "bad or unsatisfactory," and that an excessively small percentage of the boys become useful men.

The results of this child-incubation are most unsatisfactory; but above all, it is expensive. And this point will doubtless appeal to the American mind. It appears that each child is reared at an expense of about $150 a year in the barracks, while in cottages the expense is $125, and by the boarding-out system $65 a year. This statement becomes more exasperating when we learn that almost one-half goes for officers' salaries and only one-fourth for the "maintenance and burial" of the children.

The *London Times* has given the inquiry the support of a powerful editorial, but nowhere does anyone mention the success that has followed the boarding-out plan in Australia. This system was noticed in the THE MEDICAL NEWS of November 11, 1893, p. 551.

To us the condition of our own institutions for destitute children is of little interest. The number of such children seems to many comparatively small. In all of our large cities great colonies of gamins subsist and thrive in the streets, under the sidewalks, and in deserted mills and houses. Only those too young to run away can be kept in the eleemosynary institutions that the pious have provided. Detention is possible for those who have tasted liberty and street-life, only when committed by our unthinking courts. Thus, while England is aroused over the perversion of humanity in these barracks and workhouses, and demands a legislative investigation, America, the land without a privileged class, has not the time to discuss the subject at all. In far-away Australia the problem is solved.

It might be denied that the children of the State and their condition and education have received no attention from us. Let a few facts answer.

At a recent visit to Troy, N. Y., a new gothic orphan-asylum was discovered that cost for the building alone 125,000 dollars, and prepared to accommodate 200 children. This is a private institution, doubtless with ordinary wishy-washy charitable motives and with the ordinary inadequate, and, may we say, inhuman results. In the city of New York a Catholic institution was visited in which there were 300 inmates supported from the treasury of the city. In Pittsburg, Pa., attention was called to the fact that a young girl was then in jail for ten days for disorderly conduct on the testimony of a single police officer, and the same one who had sent in a similar way two sons of this girl's widowed mother to the workhouse for thirty days each. It was impossible to gain any admission to this girl because her sentence was a ten days' bread-and-water punishment. And what for? For going out barefoot on the streets of Pittsburg to look for her brother at 11 o'clock at night.

Scientific, unprejudiced men and women have shown beyond question:

1. That institutional life is dangerous in proportion to the size of the institution and the youth of the inmates.

2. That the children of the street are in the schools for vice and crime.

3. That the commitment of young persons and children to the jails, prisons, and workhouses of our cities is inexpedient, extravagant, inhuman, and in every way irrational.

4. That every orphan-asylum is a public curse.

5. That the most efficient, the most economic, and the most rational method of caring for destitute children is by the boarding-out plan, or Australian system.

No altruist can look with complacency upon our condition as regards the children of the State. This movement in England may, perhaps, arouse our anglo-maniacs to imitation. But only the thoughtful will hasten the time when ours shall be a country without an orphan-asylum and a land without a child in workshop, jail, or reformity. In this work medical men must be conspicuous for the honor of our profession.

EDITORIAL COMMENTS.

The Presence of Tubercle-bacilli in the Nasal Cavities of Non-tuberculous Persons.—The ubiquity of the tubercle-bacillus is already well recognized. As the dissemination of the organisms takes place most commonly through the mediation of the fine particles into which the indiscriminately-disposed-of expectorated matters or other discharges from tuberculous persons are ground, it is logically to be expected that the bacillus may be found wherever dust can penetrate. Thus it is that tubercle-bacilli have been found in washings from fruit exhibited for sale in open places, as upon the streets, and upon the walls and ceilings and in the dust of houses occupied by tuberculous subjects to the care of whose discharges the most scrupulous attention has not been given. The knowledge of these facts prepares us for the announcement made by STRAUSS (*Münchener medicinische Wochenschrift*, 1894, No. 28, p. 567) at a recent meeting of the

Paris Academy of Medicine, that he has found virulent tubercle-bacilli within the nasal cavities of non-tuberculous persons whose relations necessitated their association with and frequent presence in rooms occupied by tuberculous patients. The individuals thus studied included male and female hospital-attendants, patients that had long resided in the hospital on account of other than tuberculous affections, and finally clinical assistants. Those belonging to the first and last categories were in perfect health and presented not the slightest evidence of tuberculosis. In the cases studied observations were made of the dust, the crusts, and the accumulations of mucus in the nasal cavities, removed by means of cotton tampons mounted on wooden sticks and sterilized. The tampons and their contents were placed in sterilized water, and this fluid was then injected into the peritoneal cavity of guinea-pigs. Twenty-nine animals were thus treated with the secretion from twenty-nine persons. Seven guinea-pigs died in the course of a few days in consequence of septicemia or purulent peritonitis; nineteen of the animals remained perfectly well, and upon post-mortem examination presented no sign of disease; while nine died or were killed in from three to five weeks, and presented pronounced tuberculous lesions. Of the twenty-nine persons that furnished the material for inoculation all presented no evidence of tuberculosis, but had been for a considerable time in or about the hospital-wards. Of the nine whose nasal secretion contained virulent tubercle-bacilli six were attendants, who lived in the hospital, cleaned the wards, made the beds, etc.; one was a patient, free from tuberculosis, who had long been in the hospital; and two were clinical assistants (among seven) who spent only a few hours daily in the wards.

These observations emphasize not only the widespread distribution of the tubercle-bacillus (and of other pathogenic microörganisms as well), but also the risk of association with the tuberculous and the dangers of dust, as from the careless street-cleaning of our large cities and house-sweeping and the beating of carpets in the open air; and finally the importance of breathing through the nose, for as is well-known the nasal passages act as a filter for the air that enters the lungs and stands as a barrier to the entrance of solid particles, animate or inanimate, whose presence might occasion mischief. It would be interesting to determine whether or not tubercle-bacilli are present in the nasal cavities of persons whose relations do not bring them in contact with tuberculous subjects or expose them to distinctly tuberculous surroundings.

"The News" and the American Medical Association.—We are sometimes asked "Why does THE NEWS devote so much space and emphasis to the affairs of the AMERICAN MEDICAL ASSOCIATION and of its *Journal?* Of what benefit to medical science are ethical discussions?"

We devote space and emphasis to the affairs of the AMERICAN MEDICAL ASSOCIATION because we consider it our duty and the duty of every physician in the United States to endeavor to strengthen that Association, improve its organization and increase its usefulness. Organization is necessary to the exercise of function and the accomplishment of ends. The physicians of America, as a body, have certain legitimate functions to perform and ends to accomplish which demand organized, systematic, concentrated effort; and the AMERICAN MEDICAL ASSOCIATION, because of its comprehensive, representative, democratic character, is the best agency through which to bring about the organization of the profession, and by which and in which to do the work and attain the purposes of such an organization. Among these purposes are the bringing together of co-workers in sanitary and medical fields, the consideration of means by which the status of the profession may be elevated, the creation of proper public sentiment upon questions of State medicine, and many others that need not be here repeated, as we have often stated them.

We have devoted some of our space to criticism of the *Journal of the American Medical Association* because we recognize in the *Journal*, properly conducted, a most effective means for carrying out the high purposes of the ASSOCIATION; because we wish to see the *Journal* as good as it can possibly be made; because we conceive that the *Journal* must fail to win the respect of the profession or to exert a good influence, just in that degree that it departs from the highest standard of journalistic and medical conduct.

We believe that ethical discussions are of benefit to medical science, because unethical conduct retards the development of medical science; and hence in exposing and emphasizing the true principles of medical ethics we assist in removing obstacles from the path of science. To permit sham or fraud or unworthy pretence of any kind to go unrebuked is to offer a reward to the two greatest foes of all science and all progress—namely, ignorance and knavery. Therefore, without at all diminishing its labors in matters more directly pertaining to medical science and medical art, THE NEWS trusts to have the continued support of its readers in its continued endeavors to uphold the true interests of THE AMERICAN MEDICAL ASSOCIATION and of *The Journal of the American Medical Association* and in its contest against ignorance and knavery.

We are still patiently awaiting the publication of the full official text of the report of the Judicial Council on the complaint of the MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA. It is a matter of much interest, and there should be no unnecessary delay in acquainting the profession with the action of the Council and its reasons therefor. In this connection we call attention to the clear and judicial editorial which, in another column, we quote from the Journal of the Lehigh Valley Medical Association.

The Influence of the Liver in the Development of Pancreatic Diabetes.—Although we have learned that certain lesions of the central nervous system and destructive changes in the pancreas respectively are attended with glycosuria, the etiology and pathology of diabetes mellitus are yet unexplained. Whatever the chemic and metabolic changes upon which the excretion of sugar in the urine depends, there is evidence that no small part in the morbid process is played by the liver, of whose multiplicity of function we really know comparatively little. There is good reason for believing that under normal conditions the liver either stores up or converts into other bodies a substance allied to sugar, and which, under certain morbid conditions, appears in the urine as

glucose. Additional evidence of this influence of the liver in the development of diabetes is furnished by the results of some experiments detailed at a recent meeting of the Berlin Physiological Society by MARCUSE (*Münchener medicinische Wochenschrift*, 1894, No. 28, p. 564), who undertook to determine if the diabetes that appears after extirpation of the pancreas manifests itself in case the liver is also removed. As the animals experimented with were likely to die sooner in consequence of the two operations than after extirpation of the pancreas alone, the question arose as to whether or not the animals would live long enough to afford time for the development of the diabetes. To decide this point, a series of observations were made upon nineteen frogs. It was found that in the twelve of these in which diabetes developed, this appeared within the first day or two, the animals living on an average for five days. The proportion of sugar contained in the urine, as determined by polarization, equalled 0.4 per cent. In a second series of almost parallel cases, both liver and pancreas were removed, with the result that in not one of the animals did diabetes develop. These animals lived for from one to five days after the operation. The amount of urine excreted was considerable, though not so great as in the case of the animals from which only the pancreas had been removed. In explanation of the influence of the liver in the development of the diabetes that follows removal of the pancreas, it is suggested that there is formed in the liver a substance that, while not itself sugar, is yet of importance in the development of diabetes (perhaps a sugar-forming ferment), or that certain elements in the blood that are acted upon by the liver remain in the circulation after extirpation of this organ, and bring about decomposition of the sugar present after extirpation of the pancreas.

Quack Nurses.—Quackery is contagious and widespread. There are quacks not only in medicine, but the infection seems also to have invaded the profession of nursing. From Detroit comes the announcement of the organization of a "Correspondence School of Health and Hygiene," which proposes to give "instruction by the correspondence method in the care of the sick." The course of instruction, it is believed, "if thoroughly studied by a reasonably intelligent person, will render the pupil as truly a trained nurse as the great majority of those who come from the training schools. . . . No previous training or study is required other than the ability to read and comprehend." As to age, sixteen is not considered too young nor fifty too old. It needs scarcely be said that the art of nursing is not to be acquired by correspondence, from reading, or even from didactic lectures; these measures may aid in the comprehension of the principles upon which intelligent and rational nursing is based, but actual experience by the bedside, in the hospital-ward, and in the sick-room, is absolutely essential.

The Abuse of Dispensaries and Hospitals.—In an effort to correct the prevailing abuse of the privileges accorded by dispensaries and hospitals, the Medical Charities Committee of the British Medical Association has had printed notices for distribution among the institutions of London, with the request of display in a conspicuous place, stating that as these institutions have been "established to relieve only those persons who are too poor to pay for suitable medical and surgical aid, ... patients will be required to give information as to their means and circumstances, with a view to prevent the abuse of this charity by persons who are well able to pay." A canvass of the various institutions reveals the fact that the majority are in favor of the adoption of some such regulation as that proposed, many having already similar measures in operation; others have the matter under consideration, while none has absolutely rejected the propositions made. The example is one that American institutions could follow with advantage and dignity.

Immoral Massage.—The infectiousness and the wide distribution of evil practices is demonstrated by the fact that the revelations made by the *British Medical Journal* in connection with a form of immorality practised under the designation of massage, as noted in THE NEWS of August 4, have already been followed by the apprehension by our Philadelphia police of a number of persons on the ground of having engaged in practices of a similar character. The event also illustrates the important relation borne by the medical profession to the morals of a community.

The Infectiveness of Meat from Tuberculous Animals is a question concerning which there has been a good deal of discussion, without, however, unanimity in the conclusions reached by different observers. As the result of an analysis of the existing literature on the subject, LECLAINCHE (*Revue de la Tuberculose*, 1894, No. 3, p. 133) announces it as his belief that such meat may in certain cases be dangerous; but this is exceptional, and that even when so the danger is but slight.

SELECTION.

THE AMERICAN MEDICAL ASSOCIATION AND ITS JOURNAL.

AT the recent meeting of the American Medical Association, in San Francisco, a resolution was adopted seeking a personal interest of every physician in the country in the Association. This is a consummation devoutly to be wished if the American Medical Association will strive, as an organization, to be governed by the true principles of justice, ethics, and morals, so as to offer, in its associated effort, the true standard for the American medical profession. Any departure from this standard makes it desirable to restrict the influence of the Association in direct ratio to the amount of departure.

Because of this resolution and in a spirit of kindly criticism it is desired to point out a piece of dangerous sophistry in one of the most important documents presented to the Association. As the report was adopted by the Association and becomes its opinion, the power for harm is limited only by the influence the Association is able to exert.

It so happens that this position is taken because of previous criticism on the conduct of the *Journal* of the Association, and it has been asserted that the objections made were not honest in their purpose, but simply a covert attack to prevent the business success of the

Journal, instigated by a rival medical journal. . . . . It is believed that a false position has been taken, and the true and the good can never be attained by sophistry. . . . .

The parts to which exceptions are taken are the *reasons given* for accepting advertisements of a certain kind for the *Journal*. The Trustees say *apropos* of the conduct of the *Journal*: "The policy adopted was, that having entered upon the business of publishing a journal, we would be governed by the same rules followed by those considered reputable who were engaged in the same business." If the American Medical Association is publishing its *Journal* for the *business* there is in it, the sooner it gives up the business and confines itself to its proper sphere, the better for all parties concerned. As well might the Association order the Trustees to operate a factory for the preparation of medicines. If the Association publishes its *Journal* for the benefit of the members in presenting the transactions and other articles of value to its readers, there may be many a "business scheme" judged legitimate on the street that would and should be beneath the tone of the American physician to adopt. Whatever the standard of the other American weeklies may be, they do not, of necessity, afford precedent nor excuse for a journal of the profession, by the profession, for the profession. . . . .

It is not to be inferred that the methods employed by other journals ought not to be studied, nor that they cannot be servilely copied if that is deemed best; the point to be emphasized is that the responsibility for any method adopted in the conduct of the *Journal* cannot be shifted either to the nervous backs of American publishers or the brawny shoulders of our cousins on the other side. The responsibility rests solely upon the Trustees, and the standard by which judgment will be measured is the standard of right, and not of the example of other men. A generalization of this reasoning will permit of any practice however despicable, since "those considered reputable" by the person desiring to do the act can certainly be found.

This article does not propose to discuss the rectitude of admitting the advertisements objected to, as this phase of the question is nowhere suggested in the report.

The second reason advanced savors of a mild flattery, possibly pleasant in inverse ratio to its truth. The readers of the *Journal*, it says in effect, are sufficiently wise as to what will serve their own interests, and no care need be taken by the Trustees as long as they do not permit reading notices. Use the same argument under slightly changed circumstances to get its full meaning. The readers of the religious weeklies comprise the more intelligent portion of the community; they are "capable of discriminating as to what would serve their interests," why should the management exclude the advertisements of "Blowhard's Asthmatic Balsam," "Sneezeham's Catarrh Conqueror," or any of the other numerous remedies of that nature. Business men ordinarily do not advertise merely for sentiment; if they thought that the readers of any journal would in the exercise of their discrimination abstain from purchasing their wares it would be difficult to secure a renewal of the contract from that house.

The third argument may be seen in the following: "Had the apparent intention of those who censure our action been established, we would be obliged to present you to-day a considerable financial deficit." It is fair to infer the possibility of an exclusion of these advertisements were it not for fear of this deficit, and that a sum of money was, after all, the impelling motive for the action of the Trustees and this, their defence. Let us then examine the accounts and try to estimate the price asked for the tacit influence of the *Journal*. According to the report the net receipts were $14,969.67, and a balance of $1885.10. This means that $13,084.67 was needed to supplement the appropriation from the general treasury. The Treasurer's report shows an increased balance over the previous year of $462.85, which makes the actual sum needed but $12,621.72. This is the *maximum* price at which the *Journal* is held; but most of the advertisements are unobjectionable; the threatened deficit is very much smaller than this, and the price is correspondingly reduced.

The outcome of this analysis of the arguments of the Trustees enables the following tabulation of the principles of the conduct of the *Journal*:

I. If journals "considered reputable" are pursuing a certain line of policy, we will follow regardless of ethics or morals.

II. If we believe our readers to be able to discriminate "as to what would serve their interests," it is no concern of ours as to the character of the advertisements received, if we do not "puff" them.

III. If it is necessary to make the *Journal* pay its way, we are willing to sell its pages to accomplish this. Our price for the past year was less than $10,000.00; rather a small price for the *Journal* of the American Medical Association if it should be bought at all.

It is not necessary to moralize upon this; the simple statement of the arguments advanced, cleared from the beclouding rhetoric of the report, permits the lessons to be easily seen.—*Lehigh Valley Medical Magazine*, vol. v, No. 4, p. 214.

REVIEWS.

Medical Jurisprudence, Forensic Medicine, and Toxicology. By R. A. Witthaus, A.M., M.D., Professor of Chemistry, Physics, and Hygiene in the University of the City of New York, and Tracy C. Becker, A.B., LL.B., Counsellor-at-Law and Professor of Criminal Law and Medical Jurisprudence in the University of Buffalo. In four volumes. Vol. I. Large 8vo., pp. 845. Illustrated with woodcuts and two lithographic plates in colors. New York: Wm. Wood & Co.

On entering upon the publication of an extensive treatise in this field, the publishers have acted wisely in providing legal as well as medical editorship, and in securing the services of numerous collaborators. Such methods, of course, are seen in all fields of science; departments that had just become specialties a score of years ago, are now subdivided into specialties, and when we note this increasing tendency we are reminded of the story of the grammarian who had devoted his life to the study of the Greek definite article, and on his deathbed regretted that he had not limited himself to the dative case of it.

The introduction, comprehending nearly three hundred pages, discusses the legal relations of physicians and a summary of the laws governing the practice of medicine. It is in this latter portion that we can notice a considerable advance. Twenty years ago such a chapter would have been very brief, as there were but few laws on the subject. The information furnished is concisely arranged and makes interesting reading. One of the most valuable chapters is that on the rules and practice of courts concerning communications between physician and patient. It is pointed out in the concluding remarks of the chapter, that the laws making such communications "privileged," that is, not allowed to be disclosed in court, are by no means unalloyed benefits, as the full presentation of facts is often prevented.

The medical part of the volume is largely devoted to the various causes of death other than poisoning; this latter, of course, will be fully considered in a subsequent volume. As another evidence of progress, we note some thirty pages devoted to the effects of electricity, in which lighting and motor currents are fully considered.

Ample space is given to the description of the methods of conducting *post-mortem* examinations and to questions of identity.

Not the least valuable part of the work rests in the fact that it utilizes fully the extended experience of the courts of the United States, and thus presents to the American physician a more vivid picture of medical jurisprudence than can be obtained from works exclusively foreign.

Except in the chapter on wounds, there is little opportunity in the present volume for illustrations, but it contains two excellent colored plates. There is a little confusion in the explanation of Plate II, which shows an *ante-mortem* and two *post-mortem* burns.

The general typography of the work is good, and it may be expected to take a high rank among the manuals of its class.

Die causale Behandlung der Tuberculose: experimentelle und klinische Studien. Von Edwin Klebs. Mit eine Photogravure, sieben farben- und neunzehn Kurventafeln, vier Figuren im Text und einen statistischen Beilage. 8vo., pp. 629. Hamburg und Leipzig: Leopold Voss, 1894.

The active interest that the author has taken, not alone in the study of the pathology of tuberculosis, but, since the introduction of tuberculin, in its therapeutic management, speaks for the value of the book as a contribution to the literature of the subject.

The work is divided into two parts:

Part I deals with the general pathology of tuberculosis, including the history of the disease, the course of the disease, the action of tuberculin upon animals, the histology of healing tuberculous lesions, and the chemical constitution of Koch's tuberculin, with methods of purification and its physiologic activity.

Part II considers the treatment of tuberculosis in man with bacterial products; the bacterio-therapy of tuberculosis, including a comparative study of tuberculosis in man and in animals; the classification of tuberculous processes in man according to their stages of development; the "first, second, third, and fourth" stages of tuberculosis; *tuberculocidin* and its employment in the treatment of tuberculosis; Appendix I, reports of other physicians upon the treatment with *tuberculocidin;* II, supplementary observations, etc.

From the headings cited it is manifest that the book contains much of practical interest. Tuberculocidin, the body obtained by Klebs from cultures of tubercle-bacilli, and used in the treatment of tuberculosis, is, according to him, the active therapeutic agent contained in crude tuberculin. It is obtained from tuberculin by chemical processes, and is claimed to be entirely free from the substances to which may be attributed the undesirable results frequently occurring from the use of ordinary tuberculin.

Methods of Pathological Histology. By C. von Kahlden, Assistant Professor of Pathology in the University of Freiberg. Translated and edited by H. Morley Fletcher, with an Introduction by G. Sims Woodhead. Pp. 171. London and New York: Macmillan & Co., 1894.

This excellent treatise, which first appeared as a supplement to Ziegler's *Allgemeine und specielle Pathologische Anatomie*, will in its translation be welcomed by pathologic histologists of this country and England. With admirable judgment the author has embodied in his book only such methods as are practically useful, and not those long since abandoned. He prefers celloidin to paraffin for purposes of imbedding. It is, however, not necessary, we think, to use two solutions as recommended. A single solution, of medium consistence, will be found sufficient, even for such delicate tissue as the lung.

The author rightly deprecates staining in bulk, a method gradually falling into disuse, as "special color-reactions corresponding to definite tissue-changes," are discovered. The various methods of staining are given concisely, but with sufficient minuteness for practical application in the laboratory. The chapter on the examination of bacteria is an excellent one. We are somewhat surprised, however, to note that under Gabbet's method of staining the tubercle-bacillus, immersion in cold carbol-fuchsin for only two minutes is recommended.

The methods for examining the blood receive proper attention. Preference is given to Toison's fluid for diluting the blood in counting the corpuscles.

A brief chapter on microscopic examination for medico-legal purposes is added, and will be found useful. We can recommend the book, the translation of which is excellent, as one of the best guides in pathologic histology.

Diseases of the Skin. An Outline of the Principles and Practice of Dermatology. By Malcolm Morris, Surgeon to the Skin Department of St. Mary's Hospital, London, etc. With 8 chromolithographs and 17 woodcuts. Pp. 556. Philadelphia: Lea Brothers & Co., 1894.

The author states in his preface that he has endeavored to set forth the clinical facts and the principles of treatment of skin-diseases based on the result of modern research as to their causes. The work is essentially

clinical and practical in its scope, for more extended details of morbid anatomy the reader being referred to the larger treatises on the subject.

We have no hesitation in saying that the book contains a complete summary of our knowledge of skin-diseases, and that the subject has been presented in an attractive form. The matter is quite up to date, and there are sufficient references to the studies of other observers to make the reading interesting. The book is not large, but there is a great deal in it. The information is for the most part just such as the physician in general practice requires to aid him in understanding the pathology and treatment of cutaneous diseases. In following the teaching of Mr. Morris the student or medical man may be assured that he is in safe hands. The book is one of the best of the day.

A number of original excellent chromo-lithographic plates from the author's cases add value to the work. They are from the brush of the well-known English medical artist, E. Burgess, Esq., who has done so much to depict English cutaneous medicine. There is only one criticism to make concerning this artist's work, and that is that the coloring is usually too high.

The Nurse's Dictionary of Medical Terms and Nursing Treatment. By Honnor Morten. Philadelphia: W. B. Saunders.

In glancing over this booklet our eye has caught many things similar to the following:

Cesarean (spelled *Caesarian*) *Section* is said to have been "first performed by a Dublin midwife." Of *Cataract*, "the operation is usually iridectomy." Of *Cleft Palate*, the nurse is told that "the child must be sat (*sic*) upright when fed, and a long teat employed, and the milk poured slowly to the back of the throat. It cannot suck, as it cannot create a vacuum, and the milk is liable to return down the nose. Operation usually takes place about two or three years of age." As to *Neurasthenia*, "it (the treatment) may include seclusion, in which case we get on to Weir Mitchellism"—a subject the author also fears to tackle in any other place. *Vivisection* is defined as "scientific internal examination of a living animal;" the *Argyll-Robertson Pupil*, "one which does not contract when subjected to light;" and the *Equator Oculi* as "the line formed by the lids when the eye is closed."

Lectures on Auto-intoxication in Disease, or Self-poisoning of the Individual. By Ch. Bouchard, Professor of Pathology and Therapeutics, Member of the Academy of Medicine, and Physician to the Hospitals, Paris. Translated, with a Preface, by Thomas Oliver, M.A., M.D., F.R.C.P., Professor of Physiology, University of Durham; Physician to the Royal Infirmary, Newcastle-upon-Tyne; and Examiner in Physiology, Conjoint Board of England. 8vo., pp. 302. Philadelphia: The F. A. Davis Co., 1894.

As the title indicates, the matter contained in this book represents a series of lectures upon the self-poisonings or auto-intoxications to which individuals are liable through processes of malfermentation that may occur in the intestinal tract. In very recent times this subject has attracted considerable attention, particularly in its bearing upon the induction of susceptibility to specific infections, and the opinion, supported by pretty strong argument, is now being advanced that specific infective processes of the alimentary tract are usually, if not always, preceded by lowering of tissue-resistance through either the local or constitutional action of poisons resulting from excessive fermentation, or from the occurrence of abnormal fermentative processes, the products of which act as direct poisons to the animal organism.

A large portion of the book is given to the consideration of the toxic products in urine, a subject to which Bouchard has paid special attention. The toxicity of the fluids and of the other contents of the intestines receives careful consideration, and the poisonous processes accompanying typhoid fever and cholera are also taken up in detail.

The subject is interesting, instructive, and of the utmost importance, and the book contains much upon which we can reflect with profit.

Report of the Commissioner of Education for the Year 1890–91. Two volumes, pp. xxx, 1514, and Index. Washington: Government Printing Office.

These volumes contain a large amount of statistical and descriptive matter concerning general education, both foreign and domestic, but not much of direct interest to medical teachers. The important points bearing on medical education have already been made generally known through essays by Dr. Bayard Holmes. It is to be regretted that the publication appears so tardily. It would be quite impossible to even summarize in the space available here the topics covered in the two volumes. In an account of the development of education in Southwestern Virginia, the work of Thomas Jefferson is referred to with much praise. A considerable amount of space is given to the topic of legal education in this country and in Europe.

NEWS ITEMS.

The Cholera.—One new case of cholera and one death were reported in Haarlem on August 12th, and six new cases in five other towns in Holland. Two new cases were reported at Amsterdam on August 13th, and one in Utrecht; one death in Zaandam and one in Beverwyck. The disease is also said to be spreading in Czornowitz, the capital of Bukowina. A death from cholera was reported on August 12th at Nippes, two miles from Cologne. There were reported in St. Petersburg, from August 5th to 11th, 156 cases of cholera and 101 deaths. Forty-five cases of cholera and fifteen deaths were reported in the Johannisburg district of Prussia up to August 12th. Eleven cases of cholera and seven deaths from the disease were reported in the Dantzig district on August 14th.

The Plague.—It is reported that Kitasato, the distinguished bacteriologist, who was sent by the Japanese Government to investigate the epidemic in China, has discovered what is believed to be the specific etiologic factor of the plague. This is described as a bacterium resembling that of chicken-cholera, appearing joined in pairs, found in the blood both during life and after death, and which, inoculated upon lower animals, gives rise to symptoms resembling those of the original disease, and terminating fatally.

The Consulting Staff of the Wernersville Hospital for the Chronic Insane has been constituted as follows:

Physicians: Dr. William Pepper, Philadelphia; Dr. William W. Guilford, Lebanon; Dr. W. F. Muhlenburg, Reading.

Surgeons: Dr. DeForest Willard and Dr. William W. Keen, Philadelphia; Dr. W. Murray Weidman, Reading.

Gynecologists: Dr. Anna E. Broomall and Dr. Florence Q. McQuaide, Philadelphia.

Ophthalmologist: Dr. Charles A. Oliver, Philadelphia.

Neurologists: Dr. Wharton Sinkler, Dr. James Hendrie Lloyd, and Dr. Francis X. Dercum, Philadelphia.

The Staining of Tuberculous Sputum.—We are informed that Dr. A. L. Benedict, of Buffalo, is at work on a method of staining tuberculous sputum in bulk, so as to obviate the manipulation of the cover-glass and allow the suspected material to be deposited on the slide from a pipet.

The American Gynecological and Obstetrical Journal is the name by which the New York *Journal of Gynecology and Obstetrics* will hereafter be known.

Max v. Pettenkofer has resigned the chair of hygiene in the University of Munich, and has been succeeded by Hans Buchner.

BOOKS AND PAMPHLETS RECEIVED.

The Relation or Coincidence of Diseases of the Upper Air-passage to those of the Genito-urinary and Rectal Organs. By J. G. Carpenter, M.D. Read before the Mississippi Valley Medical Association. Cincinnati, 1892.

Lehmann's Medicin. Hand-Atlanten. Band IV: Atlas der Krankheiten der Mundhöhle, des Rachens und der Nase. Von Dr. Ludwig Grünwald. München: Verlag Von J. F. Lehmann, 1894.

A Supplementary Paper upon Supra-vaginal Hysterectomy by the New Method, with Report of Additional Cases. By B. F. Baer, M.D. Reprinted from the Transactions of the American Gynecological Society, Vol. XVIII, 1893.

Treatment of Myopia without Glasses. By W. H. Bates, M.D. Reprinted from the Medical Record, 1894.

Tumors, Innocent and Malignant. By J. Bland Sutton, M.D. Philadelphia: Lea Brothers & Co., 1893.

A Case of Ringworm of the Scalp Simulating Alopecia Areata. By Henry H. Whitehouse, M.D. Reprinted from the Journal of Cutaneous and Genito-Urinary Diseases, 1893.

State and Municipal Control of Infectious and Contagious Diseases. By John Winters Brannan, M.D. Reprinted from the Medical Record, 1893.

Incompatibility. Lecture delivered before the Medical and Pharmaceutical Students of the University of Texas. By James Kennedy, Ph.G., M.D. Galveston, 1893.

A CONTRIBUTION TO THE STUDY OF THE ACTION OF CHLOROFORM.[1]

BY EDWARD RANDALL, M.D.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE UNIVERSITY OF TEXAS, ETC.,

AND

DAVID CERNA, M.D., PH.D.,
DEMONSTRATOR OF PHYSIOLOGY AND LECTURER ON THE HISTORY OF MEDICINE IN THE UNIVERSITY OF TEXAS, ETC.

WE firmly believe that a clear understanding of the physiologic actions of chloroform on both the circulation and the respiration, especially as regards the relations existing between these two functions under the anesthetic, independently of the influence exercised by the drug on the nervous system, is not only of the deepest interest to the physiologist, but also of the greatest practical importance to the clinician. Through failure of which one of these two vital functions, the circulation or the respiration, does chloroform bring about a fatal result? This is the question at issue, a question of absorbing interest.

There are both surgeons and physicians who boast of never having met with a single death under chloroform-anesthesia. Yet, under the keenest observers and the most careful anesthetizers, death has occurred unexpectedly and in an inexplicable manner, even before the operator had an opportunity to use the knife, and in these cases the fatal result could not be ascribed to surgical shock. The statistics so far published regarding the percentage of deaths caused by chloroform, although valuable to a certain extent, are practically unreliable, and for reasons that need not be discussed here from fear of prolixity. It has been stated somewhere that Billroth met with his first death after 12,500 successful chloroformizations. We have the authority of Wood[2] for saying that according to Lyman the ratio of deaths in chloroform-anesthesia is 1 in 3860, while Richardson puts it at 1 in from 2500 to 3000. Neve[3] has reported 3000 chloroform-administrations without a single death, and Henderson[4] gives 12 deaths as occurring in 17,666 inhalations by the drug. In an exhaustive collection of chloroform-administrations, Julliard[1] reports 161 deaths in 524,507, or 1 in 3258 anesthesias. Foy[2] publishes a total of 877,507 chloroform-inhalations, with a mortality of 204, that is 1 in 4301. Valuable statistics have been presented by Gurlt:[3] in 94,123 administrations there were 36 deaths, or 1 in 2614; before this he had collected 6 deaths in 22,656 inhalations, or 1 in 3776.[4] Quite recently, Gurlt[5] has reported 46 deaths in 133,729 chloroform-administrations.

Be all this as it may, it is certain that the question of how chloroform kills remains practically a mooted one; and this is our chief excuse for trespassing upon the patience of the profession by offering the results of our individual experience in the matter—an experience based on a special research on the lower animals. Our investigation is not perhaps an elaborate one, but the uniformity of the results obtained in our experiments is sufficient, we believe, to justify us in expressing an opinion somewhat, though not wholly, contrary to the one we had previously entertained. We hope our confrères will express their individual experience and views upon the question, especially from clinical observations, and thus contribute to the elucidation of a subject so ably treated experimentally by authorities like Lauder Brunton, Wood, Hare, and others.

Before the report of the first Hyderabad Commission, it had been the general belief among clinical observers that chloroform destroyed life mainly through cardiac failure. The Hyderabad Commission, however, from a series of experiments upon the lower animals, affirmed that the drug killed by an action upon the respiration, a statment that met with considerable opposition. As a consequence, a second Hyderabad Commission, headed by Lawrie and Lauder Brunton, under the auspices of the Nizam's government, reinvestigated the subject, and, with slight differences, arrived practically at the same conclusions—that is, that chloroform always arrested the respiration before the heart.[6] This almost unqualified statement led Wood and Hare[7] to restudy the matter, and from experiments made by administering the drug either by inhalation or intravenously, it

was found that the anesthetic had a direct, distinct, and paralyzing influence on both the circulation and the respiration; that the respiration might cease before the heart, or that both cardiac action and the respiration might stop together; and, finally, that in some instances the heart was arrested before the respiration, the latter at times continuing as long as one and even two minutes after the blood-pressure had reached the abscissa-line.

Cushny,[1] from the results of another experimental research, could not agree with the Hyderabad Commission, that the heart always continued to beat after respiration ceased, and found it very difficult to maintain the concentration of the chloroform necessary to paralyze the heart simultaneously with the respiration, believing from this that such a simultaneous arrest can never occur. A similar view is entertained by Buxton,[2] an eminent authority on anesthesia, who believes that in the human subject at least death takes place during chloroformization from cardiac paralysis.

In his address on "Anesthesia" before the Tenth International Medical Congress, held at Berlin, Wood[3] reported another series of experiments made by himself, and again drew the conclusion that chloroform is capable of causing death by either primarily arresting the respiration or by primarily stopping the heart, but that commonly both the cardiac and respiratory functions are abolished at or about the same time. An identical opinion is expressed by McWilliam.[4] This investigator concludes, from his experiments, that though the respiration generally ceases before the heart, cardiac failure sometimes occurs long before the respiration is arrested.

The latest research upon this subject of which we are aware is the very elaborate one of Hare and Thornton,[5] made under the auspices of the Nizam's government. These investigators believe that the question can be settled by the acceptance of both views in a modified form; or, in other words, that there is no real antagonism in the belief that chloroform kills by depression of the heart or by depression of the respiration. They very positively assert that chloroform practically always kills by failure of the respiration when administered by inhalation, provided (and this they consider a most important provision) that the heart of the anesthetized is healthy and has not been rendered functionally incompetent by fright or violent struggles; or, again, by marked asphyxia. And as positively as they assert that the drug destroys life by primarily causing failure of the respiration, they also assert that in excessive doses by inhalation chloroform has a depressant effect on the circulation, which is chiefly due to centric vasomotor depression, with final depression of the cardiac muscle itself.

Before such a mass of contradictory experimental evidence, what are we to believe? We might venture to say by way of preface to our own conclusions in the matter, that, in the face of the discordant results obtained in the laboratory so far, every medical man, in administering chloroform to the human subject, should follow his own good judgment and study carefully each individual case. It is disastrous in many instances to blindly follow, by a sort of routine practice, the teaching of this or that authority. But we shall discuss this point later.

During the past winter we have conducted a series of experiments exclusively on dogs, and without paying particular attention to the manner by which the various phenomena on the circulation and respiration are brought about under the action of chloroform (a subject that has already been investigated by a host of able experimenters). It has been our chief aim to study how death is produced by the drug primarily, whether by failure of the respiration or by cardiac paralysis. The anesthetic was administered by *inhalation* exclusively, in a concentrated form, through the *nostrils*. For this purpose a common towel-cone was used, and both the respiratory movements and the circulatory changes were registered at the same time upon the revolving drum. We confess that we began our experiments somewhat prejudiced, not to say entirely so, in favor of death by primary cardiac paralysis through the action of chloroform, but the results obtained told a different story. For the sake of illustration we detail the following experiments:

For Experiment I a small dog was used. At the beginning of the inhalation the blood-pressure was 156 mm.; the heart showed a rate of 192 per minute and the respiration 36 per minute. One minute after the inhalation had been instituted, the respiratory movements jumped to 60 per minute, and both the pressure and the rate of the pulse were reduced. The number of respirations became 90 per minute a minute and a half later, and the pulse-rate and the arterial pressure continued still lower. In five minutes more, although the respiration was irregular, the movements marked by the needle were 72 per minute; at this point the pressure was found to be 110 mm., while the heart was still beating 144 times per minute. Gradually the respiration then became full, deep, and slow, and four minutes later only twelve movements were registered upon the drum; three minutes afterward the animal was breathing four times a minute only, the blood-pressure

EXPERIMENT I.—SMALL DOG.

Continuous inhalation. Carotid artery used for connection with manometer. Respiratory tambour connected with trachea by means of a rubber tube.

Time, m. s.	Pressure, mm.	Pulse, p. min.	Respiration, p. min.	Remarks.
0	156	192	36	
1.00	148	184	60	
2.30	136	180	90	
7.30	120	156	72	Respiration irregular.
9.30	110	144	54	Respiration irregular but deep.
10.30	90	128	30	Respiration full and deep.
13 30	80	108	12	Pulse-waves somewhat larger than at first.
16.00	62	92	4	
16.30	50	86	...	Respiration ceased; blood-pressure going down steadily.
17.00	32	40	...	Pulse very small.
18.30	10	68	...	Pulse continues very small.
19.00	...	...	...	Heart still beating about once or twice a minute.
20.00	...	...	...	Applied artificial respiration for about three minutes, by compressing chest, when both the respiration and the heart's action were brought back. Under another inhalation of the drug, death ensued, the breathing, as before, stopping first.

EXPERIMENT II.—DOG, WEIGHT 10 LBS.

Carotid artery connected with manometer.

Time, m. s.	Pressure, mm.	Pulse, p. min.	Respiration, p. min.	Remarks.
0	140	210	30	
2.40	138	212	30	Inhalation begun.
2.30	90	132	60	
3.30	80	108	48	
5.40	50	92	18	
6 00	32	80	2	Pulse-waves somewhat larger than normally.
6.30	12	30	...	Breathing ceased.
7.40	8	48	...	
8.00	8	62	...	Pulse very small.
8.15	...	...	...	Heart stopped in diastole; remained irritable: blood very dark.

EXPERIMENT VI.—DOG, WEIGHT ABOUT 15 LBS.

Carotid artery connected with kymograph.

Time, m. s.	Pressure, mm.	Pulse, p. min.	Respiration, p. min.	Remarks.
0	120	142	32	Began inhalation.
1.00	118	126	36	
1.40	80	112	42	
2.30	60	90	44	
3.00	52	84	42	Stopped chloroform.
6.00	110	126	42	Resumed chloroform-inhalation.
6.30	100	120	40	
8.00	70	98	40	
8.30	60	80	32	
9.40	32	92	16	
10.00	20	80	8	
12.00	...	...	...	Both respiration and heart stopped simultaneously. Artificial respiration had no effect.

EXPERIMENT VII.—DOG, WEIGHT ABOUT 18 LBS.

Femoral artery connected with kymograph. Continued inhalation of chloroform.

Time, m s.	Pressure, mm.	Pulse, p. min.	Respiration, p. min.	Remarks.
0	140	180	30	
0.15	110	150	30	
1.00	56	96	36	
4.00	40	90	36	
5.00	32	78	20	Respirations deep.
6.30	20	38	8	
9.30	20	36	...	Respiration suddenly stopped.
10.30	10	24	...	
11.30	...	...	...	Heart still beating about four or six times a minute; it soon ceased. Opened chest; heart was found in diastole, full of black blood, and irritable to mechanical stimulation. On making disconnection, very dark blood continued to flow from femoral artery, the color of the fluid being evidently due to the asphyxia produced.

being 62 mm., and the rapidity of the cardiac beat 92 per minute. In half a minute more the breathing stopped, and then the rate of the pulse, with slight variations evidently due to cardiac weakness, and the arterial pressure continued to sink, and in two minutes afterward the needle of the manometer stood still at the abscissa-line; but it was noticed that about once or twice a minute a curve could be registered upon the cylinder, the result of cardiac activity. When the animal was thus dead to all intents and purposes, the chloroform was removed and artificial respiration applied. This was done for about three minutes, by manual rhythmic compression of the chest, the tongue at the same time being pulled out with a hook; and following this operation both the respiration and the heart's action were brought back; in other words, the animal was resuscitated. After a sufficient time, when the two vital functions may be said to have been thoroughly reëstablished, inhalation of chloroform was again applied, and similar phenomena to those described were observed, death taking place from failure of the respiration.

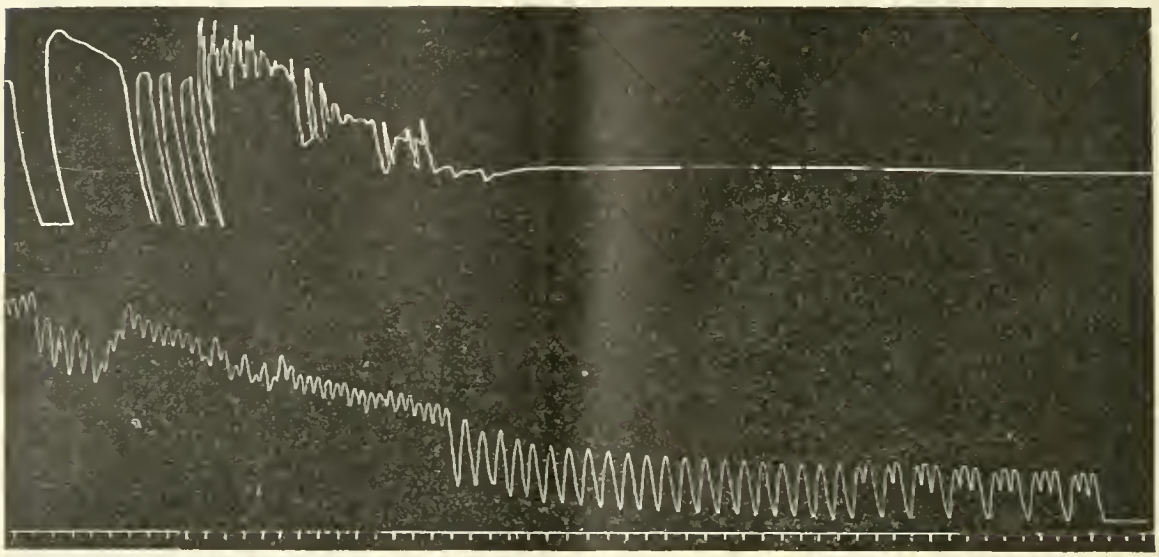
Identical phenomena were noticed in Experiment II, but (although the animal was larger and weighed more than that of Experiment I) the deleterious effects appeared sooner. In six minutes after the beginning of the inhalation, the blood-pressure was 32 mm. (originally 140 mm.) and the cardiac rate 80 per minute (originally 210 per minute). The respiratory rate, which from 30 had been raised to 60—that is, had been doubled shortly after the commencement of the chloroformization—was by this time depressed to 2 per minute, and half a minute afterward the respiration ceased, the heart continuing to beat for about one and three-quarters of a minute longer. The chest of the animal was immediately

opened, and it was found that the heart had stopped in diastole, its cavities being full of dark blood and still responding to mechanical irritation.

Experiments III, IV, and V gave exactly the same results. The respiration in each case ceased before the action of the heart.

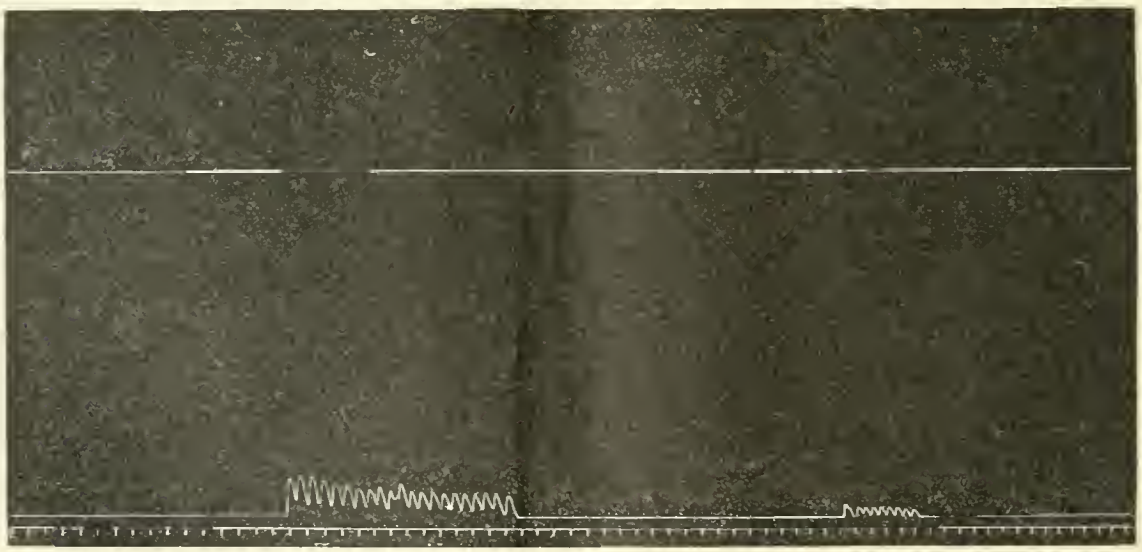
however, that the inhalation of chloroform was purposely interrupted at a period when the circulation had been considerably depressed. The withdrawal of the vapor was followed by a decided tendency of the blood-pressure and the heart's action to assume their original condition; but before this was com-

FIG. 1.



Tracing showing how chloroform causes death by respiratory paralysis. Upper line represents respiratory movements; middle line, blood-pressure and pulse; lower line, abscissa and time in seconds.

FIG. 2.

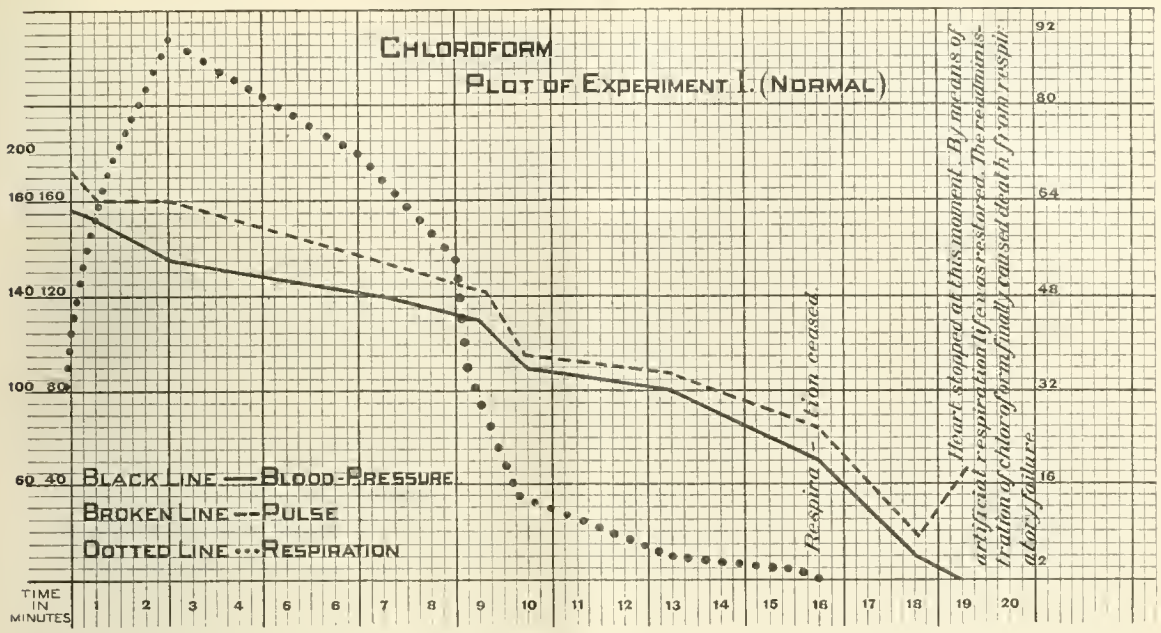


The same tracing without interruption. It will be seen that the heart ceased one minute and a half *after* the respiration.

A dog weighing about fifteen pounds was used for Experiment VI. In this instance the results were different—that is, simultaneous arrest of the heart and the respiration was observed. It may be stated,

pletely established, the inhalation of the anesthetic was resumed and the changes produced closely observed. It was seen that both pulse-rate and arterial pressure went down *pari passu* with the depression

Fig. 3.

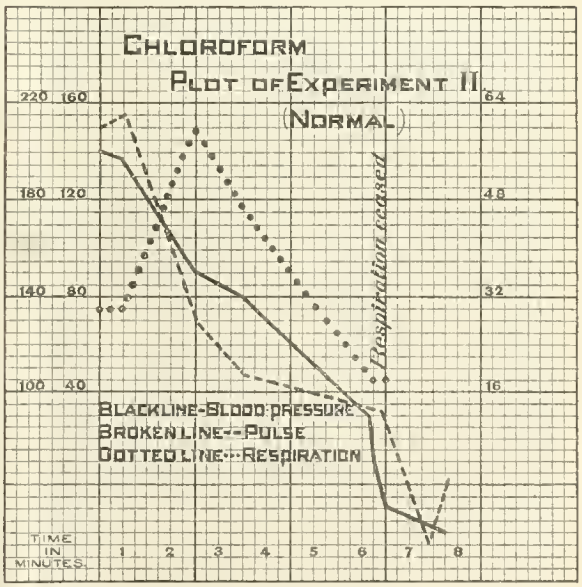


of the respiration. Six minutes after the beginning of this second inhalation, both needles, that of the tambourine and that of the manometer, came to a standstill *simultaneously*. Artificial respiration was then applied vigorously, according to the method described, but all our efforts in this direction were of no avail. Although there appeared some reflex respiratory movements and an occasional heart-beat, life could not be restored.

For Experiment VII a medium-sized dog was used. The experiment was performed before Professors William Keiller and James E. Thompson, of the University of Texas, and in the presence of the medical students of the third-year class, Professor Keiller himself administering the chloroform. The same results were produced. Following the inhalation of the drug, a lowering of the arterial pressure and of the rate of the pulse was observed. The respiration was, as usual, slightly increased in rate at first, becoming depressed soon afterward. A lowering of the blood-pressure and of the cardiac and respiratory rates was then progressive until the occurrence of death, this taking place distinctly and directly through failure of the respiration, the heart continuing to beat for about a minute and a half longer.

One of our experiments (No. V) was also witnessed by Dr. H. C. Cooke, of Galveston (and likewise of the University of Texas), who, though convinced of the accuracy of the experiment and the, to him, unexpected result of death from respiratory failure, still maintained that interference with the circulation at the base of the brain by tying the carotid artery might have some influence in enhancing, at least, the death of the respiratory before that of the cardiac centers. This, we contended, had little

Fig. 4.



or nothing to do with the result, as in the experiments of other investigators, in which the carotid artery had been frequently used for the kymograph-connection, death is reported to have occurred also primarily through cardiac paralysis. To further satisfy ourselves of this, however, and to put aside objections such as that offered by Dr. Cooke, we

made experiments by using the femoral artery for connection with the manometer. In this manner no direct interference could be had with the circulation at the base of the brain. In these cases the results were similar—that is, failure of the respiration, as exemplified by Experiment VII, detailed also in tabular form.

In this experiment, in less than one minute both the height of the pressure and the rate of the cardiac beat were distinctly diminished, although the respiration was practically unaffected. In the course of about four minutes the respiration became somewhat accelerated, the pulse-rate and the blood-pressure continuing to decline. Soon afterwards the respirations became considerably slower, having been reduced from 36 to 20 per minute. This respiratory depression continued *pari passu* with that of the arterial pressure and the pulse, and about four minutes and a half later the animal stopped breathing suddenly, but the needle of the manometer continued to write upon the revolving cylinder for nearly two minutes longer. After the column of mercury had stood motionless, the glass canula was immediately separated from the femoral artery; very dark blood continued to flow from that vessel, the color of the fluid being due undoubtedly to asphyxia; its ebbing (the animal continued to lie in a perfectly horizontal posture) showing that the heart was still working. And this was found to be the case when the chest of the animal was opened. Even after it had ceased to beat, the heart remained irritable to mechanical stimulation.

Many other similar experiments yielded the same results, but it will be unnecessary for us to detail more of them. The details that we have given are sufficient, and the few records briefly described represent the general results obtained in our experiments, results remarkable for their uniformity.

It is but fair to state, however, that in Experiment XV, the heart suddenly ceased to act, while apparently no change whatever could be noticed in the respiration. We thought that death would be the final issue in this case from cardiac failure. The chloroform was removed (the breathing continuing in a regular manner), when in a few seconds the needle in the manometer rose unexpectedly and began to record anew the heart-beats; again these stopped, to reappear after a short interval, and in about three minutes the respiration ceased, and in spite of this the heart continued to act for a few seconds longer, then finally coming to a standstill. How could this phenomenon be interpreted?—a cardiac or a respiratory failure? It was not a true respiratory failure, because even when the circulatory disturbance was marked, the respiration was apparently unaffected; and if the respiratory centers succumbed finally, it may properly be said, perhaps, that they did so on account of a diminished blood-supply and not owing to a direct influence of the chloroform. The result was not a cardiac failure in the proper sense of the term (although it looked more like it), because the heart was able to work after the stoppage of the respiration. The drug in this case acted undoubtedly more as a cardiac than as a respiratory poison. We shall consider this point later.

Another striking action of chloroform closely observed was one that has been noticed by most previous investigators, and is without question, therefore, correctly stated. We refer to the influence exercised by the drug on the pulse and the blood-pressure. It was seen (and an examination of the tabulated experiments reveals the fact) that from the very beginning of chloroformization, even before the respiration was markedly affected, there was a lowering of the arterial pressure, accompanied by a diminution in the rate of the pulse.

The respiration, though at first slightly increased in rate, became gradually depressed and generally and, we may say, practically always stopped before the heart. In not a single experiment did we see distinct cardiac failure preceding the stoppage of the respiratory function, and in only one case surely, and in a second one probably, was there noticed a simultaneous arrest of both the respiration and the action of the heart.

The general and marked results of our investigation lead us to conclude that chloroform given by inhalation and in excessive amounts, other things being equal, destroys life mainly through failure of the respiration. It is true also that during chloroformization there is considerable circulatory depression, and this latter phenomenon may likewise become exceedingly dangerous. While we, therefore, agree in the main with the results of the second Hyderabad Commission and with the similar ones obtained by Hare and Thornton, in that death from chloroform administered by inhalation to the healthy organism is due primarily to a direct action on the respiratory centers, yet we do not believe that during chloroform-anesthesia in the human being, no matter how favorable the circumstances, the respiration alone should be watched. While the disappearance of the radial pulse, for instance, is not an absolute sign that the heart has stopped beating, it is, nevertheless, a very positive indication that the circulation is much depressed. Now, it is possible for this phenomenon to be present—that is, a weakened condition of the circulatory apparatus may be so marked as to render it difficult to detect a radial pulse—and yet the respiration may continue to be apparently normal. Are we, under such

circumstances, and from the fact that the respiration has not yet shown any signs of disturbance, justified in continuing the administration of the chloroform?

Even though experimental evidence has apparently demonstrated that, under chloroformization, there is more danger from respiratory than from cardiac disturbance, it becomes our duty, it seems to us, to remove our patients not only from the main source, but from all possible sources of danger. A weakened circulation brought about by chloroformization is a source of danger, undoubtedly, and it becomes evident, therefore, that that function should not be neglected simply because we have more cause to fear a failure of the respiratory function.

Hare and Thronton state that

"As there is always a fall in pressure under chloroform, it is difficult to feel the radial or temporal pulse, and the respiratory center recognizes the degree of arterial depression which its sister vasomotor center has permitted by finding that its blood-supply is insufficient. As respiration fails first, it should be watched first. Finally, it is only by watching the respiration that we can tell how much chloroform the patient is getting. We do not watch this function for danger alone, but to tell us of the dose."

The same investigators have remarked:

"That the circulatory depression may be dangerous is not only evident, but it is stated to be so by the second Hyderabad Commission itself at the end of paragraph 8. This circulatory depression may be so profound that recovery is impossible, even with the most thorough artificial respiration, a fact stated by the second Hyderabad Commission in paragraph 25.[1] . . . This emphasizes the fact that *we cannot afford to totally ignore the effect of chloroform on the circulation*,[2] and we cannot consider the patient in danger of circulatory failure *only* when the respiration *ceases*, BUT AS SOON AS IT BECOMES ABNORMAL."

We do not entirely agree with the last part of the foregoing statements. We hold that the circulation, independently of respiratory disturbances, may become abnormal also, either through cardiac weakness or vasomotor changes, or both, and, therefore, dangerous; and we further hold that the circulation, in the large majority of cases, *becomes abnormal as soon as it becomes depressed*. In some cases this abnormality is made manifest before there is any disturbance of the respiration. The result obtained in Experiment XV is very significant, and we firmly believe that parallel instances are of more frequent occurrence in the human being, under the full influence of chloroform, than is generally supposed. Therefore, if we are to watch the respiration in every case, as advised by Lawrie, irrespective of the pulse, there is no doubt that we shall continue to increase, instead of diminishing, the death-rate in chloroform-administration.

[1] We have had a similar experience in many of our experiments.

[2] The italics are ours.

Hare and Thornton again remark:

"On the other hand, we should remember that, even if chloroform has been given properly, the arterial pressure may be so low as to give NO pulse in the radial artery, and yet the circulatory system be ready to respond at once when the drug is removed. If, therefore, the chloroform is properly administered, is there danger of its circulatory effect in man?"

—implying apparently by these expressions that, under such circumstances, there is little or no danger from a depressed circulation if "the chloroform is properly administered." But we believe that a depressed circulation, independently of any respiratory disturbances, should put us always on our guard; and for greater reasons should such a depressed circulation, particularly when carried to the extent of causing a disappearance of the radial or temporal pulse, be a sufficient warning for us to remove the anesthetic at once. Because, even granting that more often than not the circulatory system, depressed by chloroform, is ready "to respond at once when the drug is removed," we cannot tell how long we may with absolute safety prolong the administration of the agent after the appearance of the circulatory depression.

As much as we are now convinced that chloroform, administered by inhalation, produces death in the lower animals (for example, dogs) chiefly by primarily arresting the respiration, we are also satisfied from clinical observation and from the results of our experimental research, that *both the circulatory and respiratory functions should be watched at the same time*. We do not, therefore, entirely agree with this statement of Hare and Thornton:

"While watching the respiration will not warn us of a sudden cardiac arrest in fatty heart plus chloroform-depression, neither will the pulse give us such a warning; and we are confident that the statement of the Hyderabad Commission, that the *respiration should be watched*, is correct, for we believe, from a long series of observations, that gradual cardiac failure never occurs without producing respiratory changes from the very first. In other words, we do not believe that in a *healthy* heart chloroform can cause serious disorder without, as a result of beginning disorder, disturbing respiration; and, second, that in a healthy heart a quantity of chloroform sufficient to disorder it will by its direct action disorder the respiration.[1] If, as an extra precaution, one assistant watches the pulse, while the other watches the respiration, very well, for though the respiration is the more important function to watch, the man watching the pulse might discover an irregularity which the anesthetizer may not see reproduced in the respiratory action; but as divided attention generally means a slighting of both objects in view, *Lawrie is right in insisting on the pulse being let alone*."[2]

We are not justified in letting one function alone simply because its disturbance is not as dangerous as that of the other function. It is our duty by all

[1] We do not think this is necessarily the case, especially if we take into consideration constitutional idiosyncrasies, etc.

[2] The italics are ours.

manner of means to enhance the safety of our patient. It is well enough that in experimentation upon the lower animals, one or the other function, or both, be entirely neglected, *in order to determine which one stops first;* but this sort of experimentation cannot be carried on in the human being. Moreover, though experimentation upon the lower animals is the best means we have at our command for arriving at scientific conclusions, when we come to the human being we cannot proceed entirely from analogy—that is, from the results obtained in the laboratory. Again, even admitting that it has been positively demonstrated that death under chloroform occurs mainly from respiratory failure; and, on the other hand, if it be shown, *as it has been shown*, that there is danger in disturbance of both functions, no matter which one of the two is the more easily affected, it is but fair, it is but reasonable, to insist that *both the circulation and the respiration should be watched at the same time*, and not one function alone. Science and practical experience demand the careful employment of this double precaution.

Physiological Laboratory, University of Texas, Galveston.

A PLEA FOR THE EXCISION OF THE INITIAL LESION.[1]

By EDMUND E. KING, M.D. Tor., M D., C.M. Vict., L.R.C.P. Lond., etc.;

surgeon to st. michael's hospital; physician to home for incurables and house of providence; assistant pathologist, toronto general hospital.

Excision of the initial lesion as an *abortive* measure has been practised at irregular intervals since 1693, when M. Corbis, of Lille, first excised the sore, contending that the poison had not yet entered the system. Since that time some surgeons have followed his lead, but many more have opposed the treatment. Each advocate of excision has had an idea of aborting the disease, but no one, so far as I know, has advocated the procedure as a method of treatment to lessen the secondary symptoms. I hope to show that by early excision of the initial lesion the disease may be aborted, and by excision in the later stages the secondary symptoms can be moderated.

I am very sorry to disagree with any opinion expressed by my friend Dr. R. W. Taylor, but I can hardly accept his explanation of the matter as laid down in a very elaborate paper entitled "Why Syphilis is Not Aborted by the Destruction or Excision of the Initial Lesion."[2] In this paper two particular cases are referred to, and conclusions are drawn from the pathologic condition as demonstrated, but we are not justified in assuming that these conditions existed in an earlier stage of the disease. That would have to be actually demonstrated before an argument could be based on their existence. Again, the condition demonstrated must be constant and have some particular relation to the dispute in question. If the identical condition can be demonstrated in other diseases, then no conclusions of a positive nature, attributed to one disease, are justifiable. Dr. Taylor concludes from the microscopic appearance in these two cases—one of a chancre of about four days', and the other of ten days' existence—that it is owing to the rapid infiltration with leukocytes of the peri-vascular spaces and tissues immediately surrounding the bloodvessels. (Figs. 1 and 2.) I quote from his article:

"The point deserving of attention in the first case is the extremely early and far-extending involvement of the bloodvessels; although the primary sore in the first case is but of a few days' duration and very small, and under the microscope is of such limited and circumscribed extent, the bloodvessels are very extensively surrounded by cell-investment, at a considerable distance from the ulcer. The microscope shows *how very deeply rooted syphilis is at the beginning of the sore by having propagated itself along the peri-vascular lymph-spaces, and how futile it is, as experience has already shown, to attempt to stay syphilis by excising the primary sore. Apparently, judging from the appearance of the vessels in this case, their involvement begins before the appearance of the sore.*"[1]

In the foregoing paragraph no consideration is given to inflammatory change, or to the irritating effect from the development of a toxin at the site of the lesion. We know from bacteriologic studies that an infiltration of leukocytes is found in the tissues in about two hours (or less) after an irritating poison has been applied. This infiltration of leukocytes is all that has been demonstrated here. We are asked to look upon these as the poison of syphilis, but we can hardly do that. Some other conditions must be demonstrated, for instance a specific bacillus in this tissue. I have here a section made from a chancroid, removed on the second day after its development, which presents identically the same appearance as that described by Dr. Taylor. (See Fig. 3.) I shall quote one paragraph from his paper that will be an excellent description of my specimen:

"This change in the bloodvessels consists in the distention of the peri-vascular spaces with small, round cells. Nearly every vessel in the section, both artery and vein, is in this way enveloped by masses of small, round cells, forming a sheath, like

[1] Read before the American Association of Genito-urinary Surgeons, at Washington, May 31, 1894.

[2] Medical Record, July 4, 1891.

[1] Italics mine.

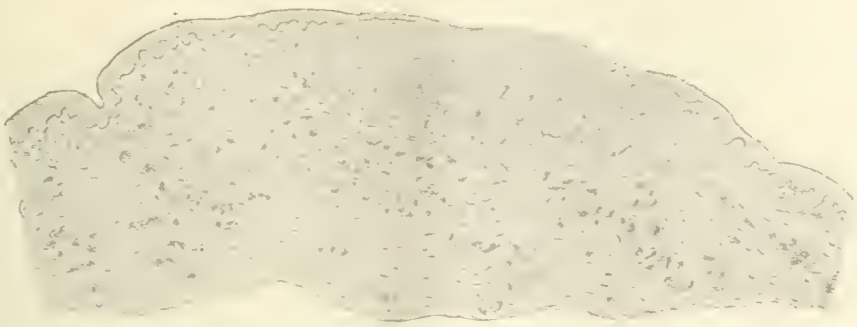
a coat-sleeve around the arm. . . . Besides this condition of the peri-vascular spaces there is a change in the endothelial cells lining the arteries and veins. The endothelial cells are swollen, and seem to be proliferating."

I shall quote one more paragraph from Dr. Taylor's article:

"These studies therefore go to show that in the very first days of syphilitic infection, as shown by the chancre after the first period of incubation, the poison is deeply rooted beneath the initial lesion, and that it extends far beyond it; that it is in a most active state, and running along the course of the vessels it soon affects all the parts beyond, even to the root of the penis. These studies seem to warrant the conclusions that the virus is not localized at the point of entry, and that it does not shut itself in by throwing out a dense wall of circumvallation which, later on, disappears and allows the exudation of the morbid products of the heretofore supposed closed-in morbid focus."

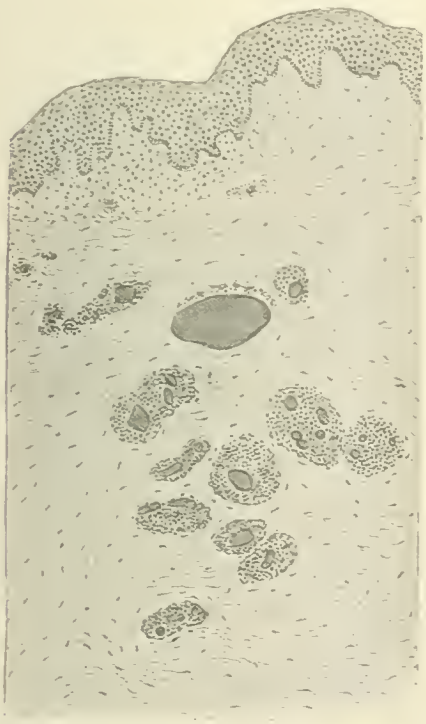
Here again the infiltration is pointed to as the syphilitic poison. From the conditions found in and surrounding the chancres, Dr. Taylor concludes that the poison is not localized in the sore. Certainly not, after a certain amount of the poison has entered the circulation, but this localized sore is a reservoir from which new poison is continuously poured into the system until the induration becomes entirely absorbed. The paper really strengthens the case of those who advise excision at any stage.

FIG. 1.



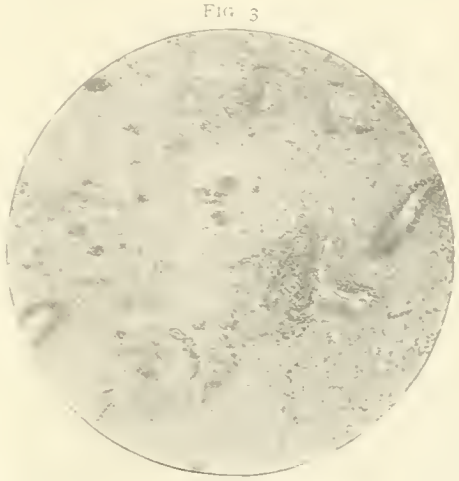
Showing the chancre (at the right upper part) and small vessels, with the coat-sleeve arrangement of the cell-infiltration in the deep connective tissue under and beyond the chancre. (Vessels represented by black dots. [Taken from lithograph illustrating Dr. Taylor's article in the *Medical Record*, July 2, 1891.]

FIG. 2.



Showing coat-sleeve arrangement of the cell-infiltration in the skin, far away from the chancre, which to the eye looks healthy. (Vessels represented by black dots.) [Taken from lithograph illustrating Dr. Taylor's article in the *Medical Record*, July 4, 1891.]

FIG. 3



From a section of chancroid, showing coat-sleeve arrangement around the vessels and general infiltration of the tissue with leukocytes.

Case I.—J. M., twenty-three years old, presented a chancre that developed twenty-two days after intercourse. He was treated by a druggist, who told him the matter was only trivial. The ulcer was very slow in healing. About six weeks after the man noticed the sore, and before it had healed, a rash appeared on his body. When he consulted me the chancre was one inch by one-half inch in size and presented marked induration. The adenitis was excessive and very painful. The rash was general and very profuse. I excised the lesion at once and the wound healed by first intention. The adenitis began to subside within thirty-six hours, and a marked change took place in the rash within seventy-two hours. I now placed the man upon specific treatment; the sequelæ were few and easily controlled. The first improvement I attributed to the removal of the cause of irritation, and the second to the cutting off of the supply of germs.

While the specific microbe of syphilis has not yet been isolated, it is almost beyond doubt that syphilis is caused by a specific germ. Although Lustgarten, Zeissl, Klebs, Doutrelepont, and Schultz, and others have all isolated bacilli, yet none has stood the test of further research, and, therefore, we cannot claim to know their absolute importance as a factor in the causation of the disease. The very long period of incubation of the disease and the peculiarity of soil necessary for the cultivation of the bacillus appear to be the most important difficulties in isolating the organism. In the light of recent researches, however, we are justified in arguing from the standpoint of a specific syphilitic germ.

In all germ-diseases there is a period of incubation of variable length. In a good many the effect of the germs is self-limited, whilst in others it is continuous. In all forms of these diseases it is necessary that the poison shall be administered or planted in a soil suitable for the propagation of the germs. That mild cases of these diseases occur proves either that a smaller dose of the germs was administered or that the soil was not properly suitable for their growth, or that both of these conditions existed together. In all cases we have a period of incubation, a period of exacerbation, and a period of recrudescence.

In the milder exanthemata the organism must grow rapidly, and the return to health is usually rapid. The introduction of the poison into the system is by a different route, we admit, and this illustrates the "one-dose-of-poison" principle. In syphilis this order of things is materially changed, and we observe a longer period of incubation, a greater time again before exacerbation or the manifestation of systemic infection, and a still greater period to exterminate the poison by Nature, if, indeed, that is at all possible—which I doubt. Here we have the germ (?) introduced through a broken surface, developing at the very point of introduction; this I believe to be capable of administering to the system, not *one dose* only, but many continuous doses of the poison.

The intensity of secondary syphilis has been held to be in direct proportion to the extent of the initial lesion. This I have corroborated, and I have further demonstrated, clearly to myself, that it is also in direct proportion to the time that the initial lesion has existed. This, it appears to me, demonstrates that it is in direct proportion to the quantity of germs introduced and the poisonous toxin generated by their growing in the system. I do not look upon the adenitis, as it appears during the continuance of the chancre, as due solely to the syphilitic poison, but to a double cause—the syphilitic germ plus an inflammatory condition due to the toxin; this is shown by the case here related, in which a subsidence occurred immediately on the removal of the sore.

I do not think that it is possible by any known means to abort the disease, once the germs in sufficient quantity have entered the general system; but I believe the course can be greatly modified by limiting the amount of the poison entering the economy. By early and free excision, the fewest possible number of germs are allowed to enter the system. In this way medical (or internal) treatment will have less to control.

Excision has been useful in other diseases in which fatal results follow the introduction of a poison, when neglected. The bite of the cobra has, by excision, been prevented from proving fatal. The excision must be practised early and freely to be successful. The effects of rabies have been prevented by free and early excision. Cauterization does not always produce the desired result. Here we are starting a new inflammation, and unless every germ is destroyed the cauterization is useless. We are producing a very suitable soil for these germs to propagate in. The same may be said of cauterizing the wound after excision, unless it be done with, say, pure carbolic acid, which does not prevent primary union.

We should excise freely and bring the edges together, and expect union by first intention. In these cases I believe that undoubtedly some poison must have entered the system, but not sufficient to be a dangerous dose. We have been shown by Biondi, Senn, Watson Cheyne, Hauser, and others, that there is a minimum dose of microbes necessary to produce systemic effects. Small doses produce no effect, and larger ones produce a greater and more rapid effect. Why not the same with syphilis?

The entire ablation of any localized diseased area is a sound surgical procedure. In these days of antiseptic and aseptic surgery it is the duty of every surgeon to render all diseased areas as nearly as pos-

sible aseptic. When excision is impossible, it is likely that free scraping may be practised and the same result attained. The free and early excision of the chancre changes an infected area into a healthy one, and removes a reservoir of growing germs that would otherwise have to pass through the entire economy. In a very short time after the chancre has cicatrized we observe the inguinal adenitis gradually subside until it attains the characteristic bullet-like hardness, and as the induration melts away this hardness also disappears, until we have left only a slight enlargement as compared with that in the first stage.

I wish it to be distinctly understood that I am not advocating the excision of chancres at all stages as an abortive measure, but as a means of lessening the systemic effects. I say again, if it is possible to see the lesion during the first few hours of its existence and to at once excise it, the disease may be aborted. Even with the ameliorating results, I do not allow my patients to be careless about internal treatment. I tell them that the treatment must be thorough, but I feel justified in assuring them that secondary results will be fewer in number and less severe in character as a consequence of the excision, and I encourage a hope that they may not appear.

I shall now report a case in which I think the disease was aborted.

Case II.—J. McK. consulted me June 18, 1893. He noticed that morning a slight crack on the free border of the prepuce. Fifteen days previously he had had sexual intercourse with a woman of the town. He was under the influence of liquor at the time. On awakening in the morning, he noticed that she had a "skin-disease on her body." He did not give the matter any particular attention, other than careful inspection of the parts. I examined the woman within two hours, and found her suffering from a secondary skin lesion and mucous patches on the vulva. I advised an immediate and free excision of the spot, which he willingly submitted to. The operation was done with antiseptic precautions and the edges of the wound brought together with fine silk. The wound healed by first intention. No hardness developed in the cicatrix, nor have any symptoms presented themselves up to April, 1894, when I last examined the man.

This case, it appears to me, furnishes as clear evidence of a disease aborted as any that has been published; yet the evidence is in some respects unsatisfactory. At the present time it is absolutely impossible to make a differential diagnosis by the microscope between a chancre and a chancroid. This case may go a long way in determining the course we should pursue in the treatment of the lesion, yet it offers no positive proof that it was syphilitic in character, although the presumptive evidence is very strong.

In six other cases the history is much the same. The wounds healed by first intention in five of them. In the sixth the wound cicatrized after some delay, as the sore had involved the border of the glans, and I did not thoroughly remove the whole of the infected area. The sores had existed for from four to fourteen days. The rash appeared very mildly in all of the cases in from forty to fifty-five days from the appearance of the chancre—four entirely escaped any other symptoms. Two had only very slight and easily-controlled mucous patches on the tonsils, but both of these patients had been inveterate smokers and had continued the habit. At least two years have elapsed since the last of this series of chancres was excised, and during the past eighteen months no secondary symptoms have developed in any of the cases.

In considering the subject of excision of the initial lesion it would be of great advantage if an answer could be made to the question, When is the system infected?

First. Is it immediately on inoculation?

Second. Is it during the incubation-period, *i. e.*, prior to the development of the lesion?

Third. Is it subsequent to the development of the lesion?

The first of these—Is it immediately on inoculation?—would, of necessity, open a purely theoretic argument for which at the present I have not the time. I do not believe that it is. All germs require time and a suitable medium for their successful development, the germ of syphilis requiring from seventeen to sixty days—a rather wide range. I know of no means whereby we can detect the slightest evidence of systemic infection immediately after the most suspicious intercourse. Nor on the closest scrutiny of many observed cases can the slightest abrasion be discovered.

In reference to the second—Is it during the incubation-period, prior to the development of the initial lesion?—again, I believe not. That period of time only has elapsed in which the germ has been able to reproduce itself in sufficient numbers to become manifest, and that at the very seat of inoculation. We have seen that a minimum number of germs are necessary to produce any result. I believe that that number only is attained when the lesion first appears. From this time the increase is fairly rapid. If it were possible to at once excise this spot I believe the system would not be infected, because sufficient of the germs have not been carried into the general system. It cannot surely be argued that the poison had entered the system, been carried throughout the whole economy and back to the very point of entrance to show itself there and there only. If the system was poisoned before the initial lesion developed, why do not lesions develop on any

sore or abraded spots that might have existed on the body during this time? If the system was infected prior to the appearance of the sore, why does it take on an average forty-two days longer for the roseola to show itself? Adenitis cannot be discovered before the appearance of the lesion, nor for some shorter or longer time after its appearance.

In reference to the third question—Is it subsequent to the development of the initial lesion?—I answer yes to this. Immediately the germ has developed sufficiently to produce the lesion, the irritation commences and the lymphatics at once take up the germ or its resulting toxin. The system is now infected, but with the very smallest quantity of poison. This is rapidly augmented and the poisoning becomes more severe. If now the sore is freely excised, possibly not enough poison has entered to produce a systemic effect, but this time must be counted by hours, not days.

The most important and most interesting question from a clinical standpoint now presents itself: Does the number of germs that enter the system in any way affect the subsequent course of the disease? If we can demonstrate this point, we have accomplished a great deal for the syphilitic sufferer. It does not sound irrational to say that a little poisonous material introduced into a suitable medium should take a longer period to contaminate the whole system than would a greater quantity. Nor does it seem to me to be irrational to say that a mild attack of any disease should be more easily controlled than a severe one. The syphilitic germ, like all others, propagates itself in proportion to existing numbers, *i. e.*, after the incubation-period has been passed there are thousands where tens existed before. Therefore we should take away any source of an increasing supply and allow the smallest number of germs to propagate themselves in the system. Nature tries to surround this infected area with leukocytes to devour the irritating and poison-producing germs; but they will not be devoured. She stands by at the glands to arrest them, but without success. Even mucous patches that occur in the mouth and on the tonsils are treated locally as much to prevent systemic reinfection as to remove the unpleasantness caused by their presence. I have endeavored to show that fewer secondary manifestations appear in those from whom the chancre has been excised than in the ordinary case in which excision has not been performed, and if this is the case, then excision is not only justifiable, but advantageous.

I have tried to base my remarks as much as possible on clinical cases, and have not attempted to quote authorities, with whom quite possibly you are more familiar than I am. I advocate the free excision of the sore; that the wound be not cauterized, except possibly with pure carbolic acid, and that the edges be united; that the operation be done with the strictest antiseptic precautions, including the after-dressing.

I would draw the following conclusions:

First, that the early excision of chancres—that is, within a few hours after their appearance—will abort the disease.

Second, that the excision of any unhealed chancre will moderate the subsequent secondary manifestations.

Third, that excision constitutes the cleanest, least painful, and most scientific method of treating the lesion.

A UNIQUE FORM OF MOTOR PARALYSIS DUE TO COLD.

By EZRA CLARK RICH, M.D.,
of Ogden City, Utah.

I wish to call attention to a family peculiarity existing in a number of my own relatives. At the present time there are living in the southern part of the State of Idaho fourteen individuals whose nervous system is peculiarly susceptible to the influence of cold. I recognize the fact that cold is a very important factor in the production of certain forms of neuritis which may result in paralysis; but paralysis without a neuritis or inflammation of any of the tissues of the body, is, I believe, a rare condition. I suppose the nervous system of almost all individuals is more or less depressed by the effects of cold, and in some it may result in slight paralysis, as of one or more fingers. Paralysis of entire groups of muscles, however, as the whole of both upper or lower extremities, without the symptoms and results of inflammation, is perhaps only found in those possessing the peculiarity which I wish here to describe.

In fourteen persons now living with whom I am well acquainted, as it was also in three who are dead, the condition is the same under similar circumstances. When brought in contact with a cold, damp atmosphere, the muscles most exposed soon become fixed and immovable, the paralysis being due to tonic spasm. The parts exposed may be fixed either in extension or in flexion. The muscles of the face are most frequently affected. The accompanying photograph, Fig. 1, shows fixation of the facial muscles; Fig. 2 shows the same individual as she is normally. The attitude may differ from this; one eye may be open and the other closed. One side of the face may be drawn up and the other be straight, or the face may be paralyzed in the act of laughing, crying, whistling, etc. I have seen one of these individuals affected while laughing and the facial muscles remain in the

attitude of laughter for twenty minutes or more, and then be only relieved by getting into a warm room. The arms are quite often affected, and come next in frequency to the face. The muscles of the fingers and forearm are generally, if not always, affected first, as a result most likely of their being most exposed. Both arms may be paralyzed at the same time, or one arm, one hand, or one finger may be

Fig. 1.

Fig. 2.

affected, and the rest of the body normal. The same is true of the lower extremities; the muscles of one or both thighs may be attacked, and the legs be normal, or one or both legs may be affected, and the thighs and rest of the body be normal. All the groups of muscles mentioned may be affected at the same time, making it impossible to move even a finger or a toe, much less an arm or a leg.

It may not be out of place here to relate a circumstance occurring in the history of one of these individuals. After dancing for several hours and becoming tired, her underclothing becoming saturated with perspiration, she retired for the night with a sister who was not affected with this peculiarity. The room was damp and there was light covering on the bed. The girl did not remove her damp underclothing, and was soon completely paralyzed, with the exception of her tongue, which on account of the warmth of the mouth escaped. While in this condition she relates that she was unable to move any part of her body except her tongue, by which she made her condition known. Respiration was not materially interfered with. The intellect was clear, and conversation could be carried on as well as other times, except that the lips were paralyzed. Sensation was not impaired, and she suffered no pain. Recovery was brought about by the application of heat, and in five or six hours she had completely recovered, without any ill effects from the previous condition. Severe forms of this paralysis, as under the circumstances just related, are not at all common; but fixation of certain groups of the muscles of the face, arms, or legs, is very frequently seen during cold, damp weather. I have repeatedly seen different individuals of this family with their upper or lower extremities in a fixed condition from cold, and no more able to move the affected part than a chronic invalid who has been paralyzed foi years. The tongue is very easily affected by taking snow or ice in the mouth. When any amount of this is swallowed, the muscles of deglutition are affected and swallowing becomes impossible.

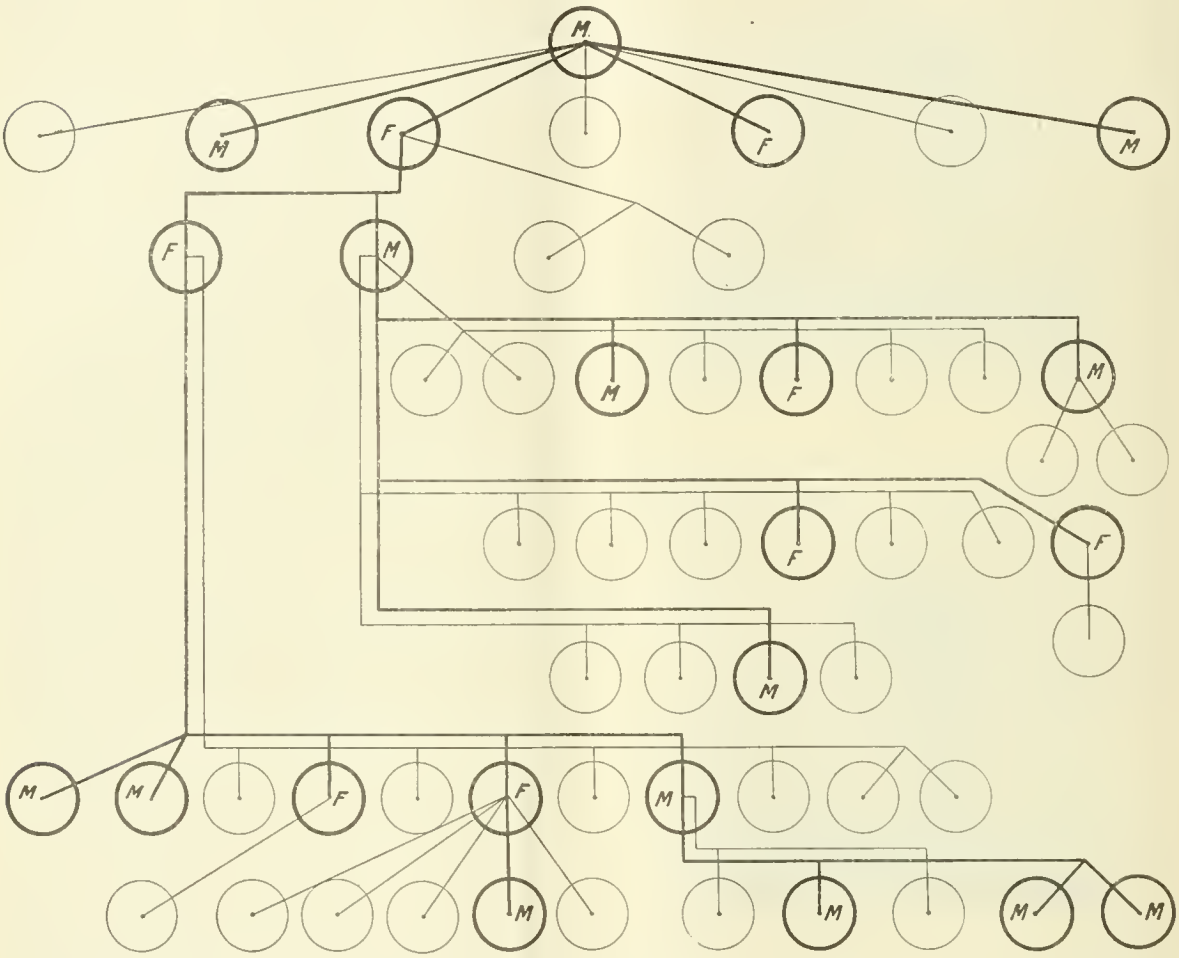
The affection seems to be only a motor disorder, the sensory nerves not being involved. Dr. E. I. Rich has carefully tested the sensation of the paralyzed parts, and finds it not in any way impaired. When the tongue is affected the sense of taste is as acute as at other times. At the onset of the paralysis there are no symptoms in the parts affected, except what the subjects describe as a "drawing sensation," especially felt in the anterior part of the thighs and the calves of the legs when the lower extremities are affected. A peculiar symptom occurring with the paralysis is an intense desire to urinate, which is almost a constant symptom. The bladder can be evacuated at this time without trouble, and the desire is not repeated. Paralysis of the sphincter muscles of the bladder and rectum, with uncontrollable evacuation of the contents of the bowel and bladder, has never happened as far as I have been able to ascertain, and I have made careful and especial inquiry regarding this matter.

Recovery from this condition is always complete, and is brought about by the application of heat, either as warm air or as the warm bath. There is no pain either accompanying the fixation of the muscles or during the recovery. In the slight forms

of the affection, as seen in Fig. 1, recovery would take place in about half an hour. When the tongue is fixed recovery is complete in a few moments; but in the severe forms five or six hours, under favorable circumstances, will elapse before the parts have recovered their strength. The return of strength is gradual; the affected part is slightly swollen or edematous and very weak and limp, but not tender to the touch. When the tongue is affected it is very much increased in size, almost entirely filling the mouth. The marked edema of this organ is probably due to its great vascularity.

the vitality of the system, as present or previous disease, exhaustion from overwork, or want of food, etc., predisposes the individual to the affection. Muscles in active motion are not affected. In walking, the arms and face may become paralyzed, while the legs would not be affected as long as they were kept in motion. If however, they were tired and the individual should sit down for five or ten minutes his legs would almost surely stiffen. I do not wish to convey the idea that these people are paralyzed every time they come in contact with cold air; on the contrary, they are sometimes able

FIG. 3.



After recovery from the severe forms of paralysis the system seems exhausted for a few hours. The feeling is described by the patients as one of "goneness"; nausea is very common, but vomiting rarely occurs. There are no sequelæ, notwithstanding the number of times these people are affected every year; there have never been any bad after-effects. The condition seems evidently one, as already stated, of motor paralysis without inflammation or its consequent results. Any condition that would lower

to stand a great deal of cold weather without being affected by it, and on the other hand they are frequently affected in the summer during damp, cold, weather. Their susceptibility seems to depend entirely upon the amount of resistance which the body has to offer.

One of the most interesting features of this condition is its distinct heredity. I am able to trace the condition into the fifth generation (See Fig. 3.) I start with T. B. C., born in Milford, Connecticut,

in the year 1773. He was one of quite a large family, two or three of whom besides himself had this peculiarity. He had a family of seven children, of whom two sons and two daughters inherited this affection. Of three of the four I am not able to give any history at the present time. The other child, one of the daughters, married and had four children, three daughters and one son. The son and one daughter inherited the peculiarity. The writer's mother was one of the daughters who did not inherit the affection. The affected male of this family was married three times. By the first wife he had eight children. Of these two sons and one daughter were affected, and one of these three, when a boy of two and a half years old, died of diphtheria. The other son is now married and has two children not affected. By the second wife he had seven children. Two daughters have the peculiarity; one of these is married and has one child not affected. By the third wife he had four children, one son having the affection. This makes nineteen children in all, six of whom inherited the peculiar form of paralysis. I now return to the daughter in the family of four. She married and had eleven children, and of them three sons and two daughters have the affection. One of the sons is married and has a family of five children, three sons being affected. The daughters are married; one has a family of five children, one son inheriting the peculiarity. The other daughter has one child not affected. This makes a total of fourteen now living (nine males and five females) and eight who are dead who have inherited this peculiar form of paralysis. I am told that there are some members of this same family living in Connecticut who have this affection, but I have not been able to get their address.

I believe the foregoing history of this curious form of motor paralysis establishes its heredity beyond a doubt. The peculiarity never skips one generation and appears in the next. The family is aware of that fact, and knows that when a child does not inherit the affection it is ended as far as his offspring are concerned. The history of the family seems to prove this statement. I have never seen anyone outside of this family having this peculiarity, and in searching for literature on the subject have not been able to find anything similar. The only affection which at all resembles the condition described is Thomsen's disease. Like the latter, it is distinctly hereditary; but it differs from this in that it is always brought on distinctly by exposure to cold, and lastly, while in Thomsen's disease voluntary movements bring on the spasm, in the affection here described voluntary movement absolutely prevents the attack.

I have known and associated with these people all my life. I have seen different ones affected numbers of times. Their condition is well known to the general public living in the section of country with them. They speak of their condition as "numbness" or "getting numb." Living as they do, in a climate where the ground is covered with snow for three or four months in the year, and where a temperature of 20° or 30° below zero is not very uncommon in winter, it can be readily understood that they know the necessity of taking care of themselves, and that exposure under certain circumstances in which other people would not be in danger would be simply suicidal on their part. There is no other peculiarity in this family that I am aware of. They are not of a highly nervous temperament; they are nearly all engaged in farming and stock-raising, this causing them to lead out-door lives. There has never been a case of hysteria, mania, locomotor ataxia, infantile paralysis, multiple neuritis, or any of the allied diseases in the family. One of the fourteen, a very strong, healthy woman now, had chorea when a child. The disease yielded readily to treatment, and has not appeared since. It seems hardly necessary to say that they are not suffering with any form of specific disease or that they are not alcoholics.

As to the nature of this affection, I believe there is little to be said. At present there has been no histologic investigation made of their nervous or muscular tissues. The absence of pain and the fact that sensation is not at any time impaired seems to eliminate the sensory side of the nervous system from being implicated. Still it may be possible that the peculiarity exists in the muscular fibers, and that the spasm is the effect of reflex action. It is more probable, however, that the affection is one of the end-plates of the peripheral motor nerves, and that the cold has its peculiar influence on this part of the nervous system. The edema of the part seems to indicate that the vasomotor nerves supplying the walls of the vessels of the part affected are implicated, allowing the serum of the blood to pass out into the surrounding tissues.

CLINICAL LECTURES.

POSTERIOR SCLEROSIS AND DILATATION OF THE STOMACH IN THE SAME PATIENT.

By J. M. ANDERS, M.D., Ph.D.,
PROFESSOR OF MEDICINE IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA.

[Reported by A. M. Davis, M. D.]

A. J., a brushmaker, fifty-six years old, gives a negative family and personal history. Five years ago, having taken two meals at one sitting and thus gorged himself with food, the man was seized with sharp, lancinating pains in the epigastrium, extending to the back below the level of the angle of the scapula, and accompanied by nausea and vomiting; the vomitus being thin and watery, mixed

with mucus, and containing particles of undigested food; it was light in color when first ejected, but became dark on standing. Medicinal treatment at that time failed to relieve the symptoms to any marked degree. The attacks were followed by intermissions, recurring usually at intervals varying from a few days to several weeks, and persisted for the same length of time. Later paroxysms were unattended with pain, but were accompanied by a sensation of constriction or pressure across the epigastrium, with nausea and vomiting. Just prior to admission sharp, shooting pains referred to the lower extremities were complained of at the time of the attacks, which still persist. Loss of flesh and strength has been steadily progressive, the bodily weight being fifty pounds less than before the onset of the disease.

On admission to the hospital (two weeks ago) the bowels were constipated, the skin harsh and dry, the urine diminished in quantity and high-colored. Vomiting has occurred daily, the amount being large (sometimes exceeding a basinful), and consisting of a watery, mucoid liquid, with a very sour, foul odor. Repeated physical examinations showed unmistakable signs of dilatation of the stomach. On inspection the fundus was invisible, the peristaltic wave being absent. Palpation elicited rumbling noises from the presence of flatus, but no splashing was detected. Percussion yielded a hollow, low-toned tympany, which extended fully two inches below the umbilicus, reaching below a transverse line drawn from one anterior superior iliac spine to the other. On distending the stomach with carbon-dioxid gas (by administering separately one-half dram each of sodium bicarbonate and tartaric acid in solution) sizzling or hissing sounds were heard below the umbilicus (as from a siphon charged with soda-water); and on having the patient swallow a small quantity of water, rushing sounds were plainly audible. To demonstrate more clearly the presence of dilatation, an esophageal bougie was passed for a distance of 63 cm., the end being palpable through the abdominal wall below the navel. In a viscus of normal capacity the length of the inserted tube should never exceed 60 cm. Chemic examination showed a total absence of HCl in the filtered gastric contents, with an excess of organic acids (lactic, butyric) and fermentation-products.

The pupils are small and unequal, myosis being the more marked on the left side. They are unaffected by light, but respond readily in accommodation, thus constituting the Argyll-Robertson sign of posterior sclerosis. There is no diminution, however, in the field of vision, and ophthalmoscopic examination fails to reveal evidences of optic atrophy. Slight temporary ptosis is apparent on the left side, but no strabismus. Examination of the lower limbs shows almost total absence of the patellar reflexes, and on having the patient stand erect, with his heels in contact and his eyes closed, an uncertain swaying or rocking motion is observed, showing some loss of coördination. His gait is characteristic, the legs being held widely separated, the left foot being thrown out forcibly, and the heels striking the ground first in their descent. Some loss of muscular sense is apparent, *i. e.*, the patient does not know how much power is required to walk.

The etiologic factors in the case are of the utmost importance. Ferrier believes tabes dorsalis to be due in every instance to syphilis, either recent or remote. Male sex, middle life, chronic alcoholism, prolonged physical labor, and repeated exposure to cold and wet are among the predisposing causes. In this patient, after considerable difficulty, we have recently obtained a clear history of specific infection of twenty years' standing.

In other well-attested cases, typical symptoms of posterior sclerosis have followed ergotism and poisoning by carbon disulphid, lead, arsenic, and other mineral poisons. It may also follow spinal injuries, or develop during the course of wasting diseases. The gastric dilatation present had for its exciting cause over-distention produced by gormandizing, though there had probably existed a predisposition in this instance.

During the course and progress of tabes dorsalis, three stages or groups of symptoms present themselves—the *preataxic*, the *ataxic*, and the *paralytic* stage, the symptoms present in this case characterizing the first or preataxic stage. Pain, which is the most marked symptom, often persists throughout the course of the disease, or it may end with the onset of ataxic symptoms; it is of a shooting or electric type, often being referred to the lower dorsal region. Later the lower limbs become affected. In this instance the patient suffered severely with attacks of pain in the lower extremities, which he attributed to rheumatism or neuralgia. Intense pain may also be complained of in the rectum, bladder, and stomach, together with band-like sensations (as of a tight belt) about the waist.

Sensation is disturbed early; there may occur feelings of formication in the hands and feet, accompanied by profuse sweating. Areas of paresthesia and anesthesia often develop, appearing first upon the thighs and perineum, and later involving the remainder of the lower, and finally also the upper extremities. Polyesthesia when present is highly characteristic, one prick of a pin giving rise to several painful impressions. Later in the course of the disease, anesthesia of the muscles, tendons and fascia is present. The deep reflexes are usually early affected, although if the lesion be limited to the dorsal cord, and the lumbar enlargement be not involved, well-marked cases may exist without any diminution of the knee-jerks; on the other hand, the patellar reflex is often absent in health and in many cases of neurasthenia.

Vasomotor and trophic disturbances not uncommonly occur during the pre-ataxic stage; sweatings (localized and general), edema of the extremities accompanied by herpetic eruptions, and in some instances alopecia and shedding of the nails, occur. A peculiar enlargement of the joints, unaccompanied by inflammatory symptoms, is highly characteristic. To this condition has been given the name of "Charcot's joint." When occurring in the knee, serum may be present in the synovial sac and float up the patella, but the fluid finally becomes absorbed. Partial ankyloses may result from absorption of the ends of long bones, lateral motion and crackling sounds being elicited on manipulation; the knee-joints are thus commonly affected.

If the sclerotic process affects the anterior cornua, paralyses result; peripheral neuritis with muscular atrophy and degeneration occurring only when other structures are involved. In this case there is much emaciation, but entire absence of joint-involvement or of symptoms pointing to motor palsy.

Ocular phenomena are equally important, the Argyll-Robertson pupil, with some ptosis, being present in this case. In some instances rapid diminution in the field of vision appears early, with color-blindness, followed by the gradual development of optic atrophy. Sometimes hearing is interfered with, and the senses of taste and smell may be perverted or blunted. Aberrant sensations are not uncommon; thus, in walking, the patient often feels as though the soles of his feet were treading on feathers, cotton-wool, or fur, a symptom that is, however, not present in this case.

The foregoing group of symptoms may almost disappear at the end of the first stage, or may persist throughout the course of the disease. The ataxic period is characterized by the peculiar gait which, when well developed, is pathognomonic of tabes. As the case advances, the peculiarity becomes more and more pronounced. To assist coördination the eyes are kept on the feet when walking; later, a cane has to be employed, and as the paralytic stage is reached the patient uses crutches or is obliged to resort to a wheeling-chair. During the second stage visceral crises are more common, and may affect the larynx, stomach, or kidneys. When occurring in the larynx, severe attacks of cough, with dyspnea and dysphagia develop. Pain and laryngeal spasm may be intense, and attacks of true angina are not uncommon. The gastric crises are characterized by intense pain after partaking of food, with violent vomiting and purging; these are present in this case. The vomited matter is small in amount, intensely acid, and has been termed by the patient "pepper vomit," in contradistinction to that due to the dilatation, which occurs in large amounts at one sitting. It is a true ataxic vomit of nervous origin. Renal crises much resemble in symptomatology attacks of renal colic. In the former, however, blood and pus never appear in the urine, and this fact, together with the occurrence of other visceral crises, the Argyll-Robertson pupil and abolition of the reflexes, tends to establish the diagnosis. When, finally, the paralytic stage develops, the patient becomes bed-ridden, and may remain many years in this deplorable state, unless carried off by some intercurrent disease.

In the beginning or *pre-ataxic* period of this disease a positive diagnosis is rarely justifiable unless ocular symptoms are present, and, when existing, the previous history of the case should always be taken into consideration. The presence or absence of patellar reflexes is of little consideration; for, as already stated, they may be abolished in a case of neurasthenia, or they may even be absent during health. If, however, lightning-like pains in the extremities are present, with an absence of the reflexes, the presence of the dread disease may be suspected.

Certain conditions may simulate locomotor ataxia. Thus, in *diabetes mellitus* there may be pain and tenderness over certain nerve-trunks with paralysis of the extensors (especially of the legs) and absence of the patellar reflexes. In this disease, however, we have a different history, with the existence of glycosuria; ocular symptoms are absent and the gait is not ataxic in character. *Alcoholic ataxia* often resembles that of posterior sclerosis, but there is a distinct history of alcoholism, together with the presence of the coarse tremor increased on voluntary effort, with an absence of eye-symptoms, and usually rapid improvement following treatment. *Peripheral neuritis* is associated with a peculiar 'steppage' gait; the extensors of the legs being paralyzed, the feet are lifted high, to clear the toes of the floor, the plantar surfaces being brought down flat. The gait of *cerebellar ataxia* is sometimes difficult to discriminate from that of posterior sclerosis; but in the first-named condition the knee-jerks are retained; there is usually great pain at the base of the brain, with persistent vertigo and vomiting, unaccompanied by nausea. Optic atrophy or "choked disc" also develops often early in the course of this affection. In *diphtheric paralysis* the gait is sometimes much like that of true ataxia; the different history and the paresis of the throat-muscles would aid, however, in making a differental diagnosis.

The prognosis of locomotor ataxia is decidedly unfavorable as to recovery. Many cases, having reached the paralytic stage, persist for twenty-five years. Often uncertain symptoms of the pre-ataxic stage last ten years before the development of ataxia. Only when the history of syphilis is recent can the prognosis be said to be at all favorable, and even then apparent cure is often followed by a relapse, with a fatal termination. From some unknown cause, cold weather seems to be unfavorable to this disease, whereas temporary improvement often occurs during the summer months.

In the patient before us the two conditions present demand separate and specific methods of treatment. On admission, lavage was promptly resorted to, the stomach being irrigated twice daily with a 3 per cent. solution of boric acid. In performing lavage in the treatment of dilatation of the stomach it is often necessary to employ a larger tube than that of ordinary caliber, because of the lodgment in and obstruction of a smaller tube by undigested particles. At the present time irrigation has been discontinued, and the patient is taking four times daily a pill composed of silver nitrate and extract of hyoscyamus, each gr. ¼. The use of the former drug may be safely continued until upward of two hundred grains have been taken. Anti-syphilitic treatment should also be begun early and persisted in. Mercurial inunctions may be employed continuously for a period of two months, together with small doses of potassium iodid (from 5 to 10 grains) three times daily for the same length of time. These may then be discontinued for one month, and be again repeated for the same period. The use of certain drugs has been shown to have an injurious effect upon posterior sclerosis; among these may be mentioned belladonna and ergot, ergotism frequently giving rise to symptoms resembling those of locomotor ataxia.

For the severe dorsal pain present, cupping along the spine often gives great relief. Many authorities claim great benefit in the treatment of this disease by the use of electricity, the faradic brush, or the constant current being applied along the spinal column.

The suspension-treatment, formerly much advocated, often does harm, and has fallen into disuse. It should never be employed when marked prostration or organic heart-disease exists.

In conclusion, it is interesting to consider whether or not the two conditions coexisting in this patient—*i. e.*, gastric dilatation and posterior sclerosis—bear any rela-

tion to one another, and, if so, how that relation is brought about. Though the matter cannot be positively determined, it is probable that locomotor ataxia was here the primary disease, and this may have served as a predisposing factor to gastric dilatation. So far as my knowledge extends this has not been mentioned by any authority as a cause of dilatation of the stomach; neither have I met with any records of cases in which the two diseases under consideration appeared together. Furthermore, it is not improbable that the tendency to gastric dilatation in this case was dependent to a greater or lesser degree upon degenerative processes in the peripheral nerve-supply of the stomach. It is well known that the sclerotic changes may extend from the posterior to the anterior cornua, an explanation being thus afforded for the paretic symptoms present in these cases.

GONORRHEA IN THE FEMALE; CYST OF THE BROAD LIGAMENT.

Delivered at the Buffalo General Hospital.

By MATTHEW D MANN, A.M., M.D.,
PROFESSOR OF OBSTETRICS AND GYNECOLOGY IN THE UNIVERSITY OF BUFFALO.

GONORRHEA IN THE FEMALE.

This patient was brought into the hospital a few days ago. Upon examination it was found that she had gonorrhea. On attempting to pull down the cervix with a tenaculum the tissues tore through like wet paper. I at once thought of pregnancy, and on inquiry learned that the patient had not menstruated for some months. The color of the cervix was also suspicious. There were a number of venereal warts which I tried to remove, but could not, as the attempt caused considerable pain. I have, therefore, had her anesthetized in order to remove them, and also to make a more thorough examination in your presence. The abdomen presents no striæ; the hymen is nearly intact; the cervix is not lacerated; so it is evident that the patient has not borne children. The vagina has not the pink color of the healthy non-pregnant state, but is more or less blue, and you will note the characteristic purple of the anterior wall. The cervix is soft and velvety, and by bimanual palpation I can find something between my hands, and now I get *ballottement* as typically as I have ever felt it.

It is an interesting point, and one of importance so far as prognosis and treatment are concerned, to know whether the pregnancy antedated the gonorrhea, or *vice versâ*. It is very doubtful if gonorrheal pus can invade the pregnant uterus by gaining access between the membranes; and, if gonorrhea reaches the endometrium and tubal epithelium, pregnancy is not likely to occur. Venereal warts are more prone to develop and to grow rapidly during pregnancy. Gonorrhea does not affect the vagina materially; in fact, some claim that gonorrheal colpitis has no existence. You can see in this case that the warts grow from the vulva, and scarcely at all from the vagina. By nipping off the warts and cauterizing their bases, this manifestation of the disease can easily be removed, and in two or three days we shall make applications of silver nitrate to the vagina, taking advantage of the occlusion of the uterine cavity by the fetal membranes to eradicate the disease.

I have seen several cases of puerperal fever that were undoubtedly due to gonorrheal infection extending from the cervix. Tait says that for every thousand fatal cases of syphilis in women there are tens of thousands of fatal cases of gonorrhea. It would certainly take hundreds of ordinary cases of syphilis to cause the same amount of agony that is produced in one case of gonorrheal pyosalpinx. Syphilis in the male is a curable disease, and in women it is rather likely to run a mild course. It is not once a year that I meet with a case of syphilis in my private practice. Gonorrhea, on the other hand, enters into about half the cases of pelvic disease that I see. Just at present I have under my care a young, healthy-looking girl, married a month ago to a man of the world. She was suddenly attacked with pelvic inflammation without any good reason, although there is a story about her catching cold while menstruating, the window being open at night. I have found a salpingitis of the right side, and a green, peculiar-appearing discharge from the cervix. I have no doubt but that the man has had a gonorrhea, and that he has infected the girl.

Our attention was first forcibly called to the matter of gonorrhea in women by Dr. Noeggerath, of New York, who in 1876 read a paper on the relation between gonorrhea and pelvic disease. His statements were laughed at at the time, and, indeed, he has modified them since; but his views were largely correct. He went so far as to claim that no man ever recovered from gonorrhea, and, therefore, that no man who had once had gonorrhea could ever have children. After Noeggerath's paper was published several physicians corroborated his statements, to a greater or less degree, but it was not until Tait showed by the results of his abdominal sections that pyosalpinx, pelvic peritonitis, and a multitude of complications are due to gonorrhea, that the truth which lay in Noeggerath's statements was accepted. It certainly is too sweeping a statement to say that gonorrhea is never recovered from. I remember being on a hunting excursion once with a young man whose woes were testified to by the numerous rags which fluttered on the bushes at each camping place; yet he has since married and had children, and his wife is a perfectly healthy woman.

CYST OF THE BROAD LIGAMENT.

This specimen is a cyst of the broad ligament, which I removed some days ago. It is known to be a cyst of the broad ligament for several reasons: 1. The ovary is found intact and separate from the cyst, as you see. The fimbriated extremity of the Fallopian tube is found in the middle of the sac. 2. The fluid contained in the cyst is clear, and not thick and cloudy like the typical contents of an ovarian cyst. 3. Finally, the proof positive that we have a cyst of the broad ligament is that the whole tumor is covered with peritoneum. It is sometimes possible to enucleate such a tumor without leaving any pedicle at all, but usually there are numerous bands of adhesion, the remains of inflammatory processes, which make the removal of the cyst a matter of difficulty.

This other specimen, curiously enough, seems also to be of the nature of a broad-ligament cyst. The whole pelvis was filled with a mass which was more or less

cystic, and by vaginal examination a number of little soft cysts could be felt behind and at the sides of the uterus. On opening the abdomen and getting my hand into the pelvis, I found an immense mass of adhesions, the tumor being bound down behind the broad ligament as usual. I could break up the adhesions, however, by reaching down behind the mass and raising the hand so as to imitate the action of a paper-cutter. This is the the usual manenver. This appendage I take to be the ovary, and as it can be separated from the wall of the cyst, the cyst must be intra ligamentary. The sacs are filled with clear fluid. The Fallopian tube of the opposite side was also distended with fluid, and was removed with some difficulty, as it was so low in the pelvis. The ovary was so firmly adherent that I could not get it out. We had to deal, then, with a hydrosalpinx of one side, and a cystic degeneration of a number of follicles of the body of Rosenmüller on the other side.

CLINICAL MEMORANDUM.

SUPPURATIVE METRITIS; ULCERATIVE ENDOMETRITIS AND METRITIS; DOUBLE PYOSALPINX AND AN OVARIAN ABSCESS; EMBOLIC PNEUMONIA FOLLOWING LABOR: HYSTERECTOMY; RECOVERY.

BY BARTON COOKE HIRST, M.D.,
OF PHILADELPHIA;
PROFESSOR OF OBSTETRICS IN THE UNIVERSITY OF PENNSYLVANIA; OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL AND TO THE MATERNITY HOSPITAL.

THE patient whose case is herewith reported was admitted to the Philadelphia Hospital a month after her delivery. She gave a history of having been ill and feverish since the childbirth. She had been taken from a squalid hovel, where she had received no care. At first glance it seemed apparent that she had not long to live. The temperature was high, the pulse rapid and feeble, the respirations hurried and shallow, the abdomen tympanitic and exquisitely sensitive, and there was profound prostration. On vaginal examination the uterus was found large, boggy, firmly fixed, with sensitive masses behind and on each side. Over a considerable area of

FIG. 1.

Anterior view: Perforation at fundus; abscess opened, to the left; abscess unopened, to the right; double pyosalpinx.

the right lung, especially toward the apex, there was diminished resonance, together with numerous fine râles. The abdomen was opened as soon as practicable. At the fundus of the womb a perforation was made into the cavity by pressing lightly upon it with the finger-tip. The ulcerative process had destroyed the muscular wall to the peritoneal covering. On both sides of the uterus, about an inch below the insertion of the tubes, were large abscesses in the uterine wall. Both tubes were distended with pus, and there was a large ovarian abscess

FIG. 2.

Posterior view: Large ovarian abscess.

on one side. The broad ligaments were much thickened, being quite an inch thick at their base. On this account the removal of the womb and the control of the hemorrhage was extremely difficult. The patient reacted well after the operation, and made a good recovery, although her convalescence was somewhat delayed by an abdominal fistula that finally, however, closed spontaneously.

It would be scarcely possible to find a more unfavorable case of puerperal sepsis for radical operative treatment. The successful issue is encouraging as an evidence that one need not necessarily despair, even in advanced cases and in involvement of important structures, necessitating the removal of all the genitalia above the vagina or above the cervix. A cure, however, by surgical treatment, especially if hysterectomy is required, is and must remain exceptional. The recent literature upon this subject, unless carefully studied in the light of personal experience, is misleading. Hysterectomy has been done successfully for puerperal sepsis when it was not at all necessary. I saw last winter two perfectly healthy wombs removed for fever after childbirth. The unfortunate women, unnecessarily mutilated, would have probably recovered much more rapidly, and certainly much more safely, under intra-uterine disinfection and stimulus and support. Several of the reported cases are also open to this criticism. On the other hand, a number of fatal hysterectomies for puerperal sepsis have not been reported. Eliminating the unnecessary operations, and, were it possible, collecting all those that have been unsuccessful, it would appear that hysterectomy for puerperal sepsis has a frightfully high mortality. But even if but one case out of a hundred is saved, the operation deserves credit, for without it, in a case really requiring the removal of an infected womb, the patient must inevitably die.

An important problem in this connection is the decision whether in a given case operative treatment promises something for the patient or is surely foredoomed to failure; and, again, whether operative treatment is really required. These questions cannot always be answered till the abdominal cavity is explored after incision of its walls. But the following rule governs my own action at present:

If there is no evidence of extension of inflammation beyond the womb itself, do not operate.

This at once excludes a large number of cases: diphtheric endometritis; suppurative metritis, in which the abscess is nearer the uterine than the peritoneal cavity; catarrhal and suppurative endometritis, in which the tubes are not involved, to the extent, at least, of closure and collection in them of pus; phlebitis; sapremia. In diphtheric endometritis the removal of the womb has in my experience had no influence on the course of the disease. I have, indeed, not yet seen such a case recover under any treatment. If the abscess in suppurative metritis is near the uterine cavity, it will probably discharge into the birth-canal, as I have seen it do. If, on the other hand, it extends toward the peritoneal cavity, exudate is poured out, the womb is fixed, and an indication is afforded for operation. The other varieties of sepsis enumerated are obviously not amenable to treatment by abdominal section. On the other hand, the septic conditions that have demanded operative treatment after labor are, in my experience, purulent peritonitis, localized or diffused; suppurative metritis; ulcerative metritis, threatening and actually causing perforation; pyosalpinx and ovarian abscess; suppuration of the infiltrated connective tissue in the floor of the pelvis and at the base of the broad ligaments. This last condition calls not for abdominal section in the ordinary sense, but for an extra-peritoneal incision above Poupart's ligament or through the vaginal vault.

THERAPEUTIC NOTE.

THE HYPODERMATIC INJECTION OF MAGNESIUM SULPHATE AS A PURGATIVE.

BY F. H. FINCKE, M.D.,
OF BALTIMORE, MD.:
ASSISTANT IN GENERAL MEDICINE AT JOHNS HOPKINS HOSPITAL DISPENSARY.

IN September, 1893, a paper on the hypodermatic injection of magnesium sulphate as a purgative, by Geo. H. Rohé, M.D., Superintendent, and J. Percy Wade, M.D., first assistant physician of the Maryland Hospital for the Insane, was read before the Pan-American Medical Congress, Washington, D.C.

The number of cases selected for observation was forty-six. The number of injections made was one hundred. In 67 per cent. the injection was successful; in 33 per cent. it failed. The dose varied from 1.86 grains to 4.5 grains. It was found that small doses acted as efficiently as slightly larger doses. In only one case was the larger dose (4.5 gr.) employed.

The shortest time for the injection to produce an evacuation was three hours, the longest fourteen.

In order to further test this remarkable property of magnesium sulphate twenty-five cases were selected, and fifty injections of from one to six grains were made. The average dose was 2.78 grains.

Whether a bowel-movement, occurring fourteen hours after the hypodermatic administration of magnesium sulphate in small doses can be considered as due to it, is, to say the least, an open question.

It will be seen that, even admitting the injection to be effective at the end of seventeen hours, in our cases the percentage of success is only eighteen, and that of failure, eighty-two.

CASE IV was usually constipated ten days, and in the habit of using enemata. The injection of one and one-half grains was followed by an easy movement in seven hours. Upon the following day, without any injection, two movements occurred.

CASE II.—On days upon which the injections were omitted, bowel-movements occurred, but it seemed that under treatment the stools were slightly softer in character.

CASES I, IX, XIV.—Subsequent observations showed the character and frequency of the stools to be the same without the exhibition of magnesium sulphate hypodermatically. In Case XIV increasing doses, from grains two to grains six, were used without any appreciable effect.

The question naturally arises: Are these bowel-movements solely due to the administration of magnesium sulphate hypodermatically, or would they have occurred without it? With the exception of two Cases II and IV, no change in the character or frequency of the stools was noticed. But considering all these cases as successful, the percentage of successes does not exceed eighteen.

In the majority of cases the results were negative.

In order to compare with the foregoing the action of magnesium sulphate given in the usual doses by the mouth, eleven cases were selected, and in these, with one exception, the results were negative with hypodermatic administration.

The results were as follows: after fifty injections there occurred in seventeen hours nine bowel-movements: one in the first hour; one in the second hour; one in the third hour; one in the fifth hour; one in the sixth hour; three in the seventh hour; and one in the ninth hour.

Taking a limit of fourteen hours as before, out of eleven cases, we have eight in which the results were successful, and two which responded in twenty hours, the character of the stools being appreciably altered. However, considering the latter as negative, our ratio is: success 72.7 per cent.; failure, 27.3 per cent.

Now comparing these results, with those of the hypodermatic administration, we have:

Hypodermatically: Success, 18 per cent.; failure, 82 per cent.

By the mouth: Success, 72.7 per cent.; failure, 27.3 per cent.

Although we do not consider the number of hypodermatic injections as conclusive, still, to us, the foregoing results cast considerable doubt upon the purgative property of magnesium sulphate exhibited hypodermatically in small doses.

In conclusion, we may say that the injections were made with solutions from tablets kindly furnished by Sharpe & Dohme, and that no local disturbance was produced, except in Case XXV, in which there occurred a small area of tenderness to pressure, which disappeared of its own accord in a few days.

Dr. C. B. Burr has resigned the position of superintendent of the Eastern Asylum, at Pontiac, Mich., to accept the superintendency of Oak Grove, a private asylum for the insane, at Flint, Mich. Dr. Burr is succeeded at the Eastern Asylum by Dr. E. A. Christian, formerly assistant superintendent.

MEDICAL PROGRESS.

Gastrostomy by the Method of Witzel for Carcinoma of the Esophagus.—Tait (*Pacific Medical Journal*, vol. xxxvii, No. 6, p. 328) has reported the case of a man seventy-two years old, who for seven months had complained of dysphagia and dull pain in the inter-scapular and precordial regions. At first only solid food caused discomfort, but in the course of four months the swallowing of liquids also became difficult. In attempting to swallow, the patient felt a sense of obstruction at two points, the first, probably spasmodic, corresponding to the origin of the esophagus, and the second being referred to a point about two inches above the lower extremity of the ensiform cartilage. Regurgitation of food occurred frequently, and the patient had lost sixty pounds in weight. An esophageal bougie encountered resistance at a point twelve and one-half inches from the teeth, but with some difficulty passed the obstruction, which apparently measured an inch and a half in length. For three weeks, at the patient's request, bougies were passed daily, causing much pain, but effecting no good. Finally the patient assented to an operation, and gastrostomy was undertaken. An incision, two and one-half inches long, was made, beginning a quarter of an inch to the left of the median line, parallel to and an inch below the costal arch. The presenting anterior wall of the stomach was incised and a No. 26 catheter introduced into the viscus toward the cardiac extremity. The catheter was then enfolded for a distance of two inches by two rows of sixteen Lembert sutures. Four stitches were introduced into the walls of the stomach, thrust through the abdominal wall and made secure after inserting the silkworm-gut sutures for closing the abdominal incision. A sterilized-gauze dressing was applied and a clamp was placed over the outer opening of the tube to prevent the escape of the contents of the stomach. Rectal alimentation was practised for the first twelve hours. Sixteen hours after the operation a nutritive injection of four ounces was made through the tube into the stomach. On the second day the injections were given every four hours, and after the third day the amount was doubled. Each injection comprised three eggs, three and one-half ounces of milk, two ounces of liquid peptonoids, and half an ounce of whiskey. Through an inadvertence the tube escaped on the second day, but was replaced without difficulty or ill result. Twelve hours after the operation the patient began to be troubled with difficulty and an incessant desire to clear his throat, probably from the irritation of the contents of the esophageal pouch above the seat of stricture. This symptom yielded to frequent irrigations of the upper half of the esophagus with a 4 per cent. solution of boric acid and an infusion of coffee. The wound gave no trouble; the silkworm-gut sutures were removed on the thirteenth day. The patient sat up on the sixth day, and walked about on the fourteenth day. It was hoped to discard the tube, using it only for the purpose of making the nutritive injections.

Coincident Intra-uterine and Extra-uterine Fetation.—Franklin (*British Medical Journal*, No. 1741, p. 1019) has reported the case of a woman, thirty-three years old, who had been in labor at term for eighteen hours, with apparently some obstruction at the pelvic brim. She had already borne five children, and always with lingering labors. The woman appeared very ill and collapsed, with pale, sunken face and anxious aspect. The pulse was one hundred and fairly good. The abdomen was very prominent, especially above the umbilicus, and also tense; there was dulness on percussion in both flanks; palpation yielded no information. On vaginal examination, the os uteri could not be felt either by the fingers or by the hand. The vaginal wall was swollen and edematous. A hard mass, about the size of a cocoanut, could be felt exactly above, apparently pushing over the posterior vaginal wall, so as almost to give the impression that it was the anterior wall. This mass was evidently between the finger and the os uteri, and had lifted the cervix beyond reach. It was slightly movable and elastic and gave the impression of being a large sarcomatous growth filling up the pelvis. Rectal examination afforded no additional information. The bowels had been freely open; there had been trouble for some time in micturition. Upon consultation it was decided to open the abdomen immediately, and an incision six inches long was made from a point about half an inch below the umbilicus. About two ounces of blood at once escaped from the peritoneal cavity. The uterus presented, and the placenta was seen to be attached to its anterior wall. An india-rubber ligature was slipped over the fundus and brought gradually into the pelvis below the uterus and appendages. An incision about six inches long was made into the uterine wall; a rush of blood followed. A full-term, living, male child was easily extracted, together with the placenta. The ligature being now tightened, the hemorrhage at once ceased. A stout wire écraseur was substituted for the india-rubber ligature, and during its application there was some more bleeding. The uterus and appendages were now removed. For safety, a stout silk ligature was also passed around the stump, in case the écraseur should slip. From the pelvis there projected a huge swelling from which the hemorrhage was rather free. On manipulation the tightened capsule of this supposed growth ruptured, and a dead, full-term fetus was liberated, the vertex being in Douglas' pouch behind the uterine stump. The fetus was rapidly removed, and there ensued a terrific and uncontrollable hemorrhage from tufts of placenta attached in Douglas' pouch and to the cecum and the intestines. The bleeding did not cease until every vestige of placenta was removed. The patient lived only half an hour after the operation, although transfusion was tried.

Scorbutus in Infants.—From personal observation and a study of recorded cases, Northrup and Crandall (*New York Medical Journal*, No. 808, p. 641) conclude that scurvy may appear at any period of infancy or early childhood, although the disease is most common between the ninth and fourteenth months. The lesions are essentially hemorrhagic in character, probably as a result of diapedesis. The most characteristic are subperiosteal hemorrhages. Hemorrhages into the muscular tissues, into the skin, and into the mucous membranes, are also more or less constant. The disease occurs in every grade of the social scale, but is more frequent among the rich than among the poor. The neglected

child that eats everything at the table may become rachitic or marasmic, but he obtains enough fresh food to protect him from scurvy. The disease rarely occurs in asylums or hospitals, because of care in feeding. Lack of fresh food is its most important cause. The use of proprietary foods and condensed milk produces more scurvy in young children than all other causes. Even fresh milk in small proportions is not sufficient to insure protection. Anemia and malnutrition are almost invariably present; a peculiar, sallow complexion is common. Scurvy is frequently superadded to rachitis, but in a considerable number of cases no evidences of rachitis are present. So-called acute rickets is, in most cases, probably in all, rickets complicated by scurvy. Pain is a constant symptom of scurvy in children. It develops early, and is usually pronounced. A varying degree of immobility of the extremities is common, and is frequently so marked as to simulate paralysis. This pseudo-paralysis disappears with the subsidence of the scorbutic symptoms. Subcutaneous hemorrhages, as well as hemorrhages from the cavities of the body, are very common, but are not necessary to a diagnosis of scurvy. The condition of the gums is characteristic. They are purplish, soft, spongy, and bleeding, and frequently show pronounced ulceration. When the teeth have not appeared the changes in the gums are usually slight, or entirely absent. Painful swelling of the lower extremities is the most common symptom; the upper extremities are rarely involved. The thigh is more frequently affected than any other part. Untreated scurvy is a very fatal disease. Recognized and properly treated, a rapid and complete cure is usually effected. The result of anti-scorbutic treatment is in fact one of the most certain means of diagnosis. Scurvy may be mistaken for rheumatism, stomatitis, rickets, sarcoma, osteitis, and infantile paralysis. The disease is of dietitic origin, and must be cured by dietetic treatment. Fresh milk, beef-juice, and orange-juice are the most effective remedies.

Paralysis following Diphtheria of the Genitals.—GAYTON (*Lancet*, No. 3691, p. 1301) has reported the case of a well-developed and well-nourished girl, four years old, who presented excoriation of the groins, labia, and vulva, in consequence of an offensive, copious vaginal discharge. The vulva and the vagina were greatly swollen and covered with a diphtheric exudation. No urine had been passed for two days and the bladder-dulness extended a considerable distance above the pubes. As exquisite tenderness was present, chloroform was administered and with a catheter a small amount of albuminous urine was withdrawn. The temperature was 96°, the countenance pallid, and the pulse feeble and slow. The throat had at no time been affected. Recovery duly followed frequent applications of a solution of mercuric chlorid, conjoined with the administration of iron and brandy and a generous diet. The albuminuria, however, persisted, and the pulse and temperature remained subnormal. In the course of a month marked strabismus was observed, together with paralysis of the palate and regurgitation of fluids through he nostrils and an irritating, noiseless cough. Later, visual accommodation was impaired and the paralysis became more universal, the typical apathetic look and bearing being very pronounced. The muscles of deglutition became involved. Much headache was complained of. Feeding by the mouth had finally to be resorted to, but death took place, apparently from the action of the poison on the bulbar centers.

Rapid Retrocession of Sarcomata after Induced Labor.—JAHR (*Centralblatt für Gynäkologie*, 1894, No. 23, p. 545) has reported the case of a woman, thirty-six years old, in the seventh month of her eighth pregnancy, of cachectic appearance, who presented a hard nodule, as large as a walnut, in the right breast, a tumor as large as a hen's egg in the right axilla, and one as large as a hazelnut above the right clavicle. Upon the pectoral muscle was an enlarged gland. Two nodules, as large as hazelnuts were present at the introitus of the vagina, two on the anterior wall of the vagina behind the introitus, and two also on the anterior lip of the cervix. Other nodules, forming a collection as large as a hen's egg, could be felt in Douglas' pouch. Frequently recurring attacks of severe abdominal pain caused the patient much distress and led to the belief that the peritoneum was the seat of metastatic growths. It was decided to induce premature labor, and this was effected by the introduction of a small amount of glycerin between the membranes and the uterus. A partially macerated, dead child was delivered, and the secundines came away without delay. Soon after the labor the accessible tumors were observed to be smaller in size, some almost entirely disappearing. The woman remained weak, and without much change in her condition death took place in collapse six weeks after the delivery. Sections of portions of several of the tumors disclosed the histologic structure of sarcoma.

Reflex Spasm of the Tongue, Lips, and Pharynx Induced by Irritation of the Great Occipital Nerve.—GALLERANI and PACINOTTI (*Neurol. Centralbl.*, 1893, No. 14; *Centralbl. f. d. med. Wiss.*, 1894, No. 19, p. 335) has reported the case of a man who had been struck upon the head twelve years previously. The site of injury was from time to time the seat of pain, both spontaneous and induced. In the stellate cicatrix a small, round, hard body could be felt, pressure upon which induced pain. There was present contracture of the muscles of the left side of the neck, so that the head was held downward and directed to the left, and there was also disturbance of speech, contraction of the lips, slight trismus, and some difficulty in swallowing. This spasmodic condition was a result of irritation induced by the presence of the foreign body, and disappeared after excision of the cicatrix at the point of union of the great and small occipital nerves.

The Seat of the Formation of Urea in the Animal Organism.—As the result of personal investigation and from existing data, KAUFMANN (*Archives de Physiologie normale et pathologique*, 1894, No. 3, p. 531) reaches the conclusion that urea exists in all of the tissues of the mammalian organism and in greater proportion than in the blood. All of the tissues seem to take part in the production of urea, although in varying degree. The liver is the most active seat of urea-formation. The production of urea seems due to processes of denutrition that take place in various tissues, and results especially from the work performed by the liver.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

PHILADELPHIA.

SATURDAY, AUGUST 25, 1894.

THE NECESSITY OF BACTERIOLOGIC EXAMINATION IN MEMBRANOUS THROAT-AFFECTIONS.

As yet the most practical results of bacteriologic research have been in the direction of the prevention of disease. Perhaps the greatest good has been accomplished in the case of Asiatic cholera and typhoid fever, but very much has been done in the prevention of all of the infectious processes.

During the past four years bacteriologic studies have added much to our knowledge of diphtheria. That the Klebs-Loeffler bacillus is the cause of this disease may now be regarded as established beyond doubt. It has also been shown that most cases of so-called membranous croup and membranous rhinitis are caused by the same organism. Anatomic lesions identical in appearance with those encountered in diphtheria may also be produced by other microörganisms—notably streptococci and other cocci—so that the diagnosis is often not to be positively made without bacteriologic examination. But it is the so-called pseudo-diphtheria-bacillus that assumes the greatest importance. This organism is found not only in cases presenting a small amount of false membrane, and likely to be diagnosticated as follicular tonsillitis, herpetic pharyngitis, etc., but also in other cases with a more extensive formation of false membrane.

When this subject first began to attract attention it was claimed by a few that the pseudo-diphtheria-bacillus was constantly present in the pharynx—a condition of affairs comparable to the presence of the bacillus coli communis in the intestine and its relation to the typhoid-bacillus of EBERTH. This extreme view is now no longer held. But the relation of the pseudo-diphtheria-bacillus to the true diphtheria bacillus has not been so clearly determined. It is claimed by ESCHERICH and many others that the former is a separate and distinct organism, but the majority of investigators in this line of research now look upon the so-called pseudo-bacillus as only an attenuated form of the true diphtheria-bacillus, identical morphologically with the true bacillus, and only distinguishable from this by the inoculation of susceptible animals, in which case it fails to kill.

If, then, this pseudo-bacillus be only the bacillus diphtheriæ shorn of its virulence, the important question arises: Can this organism take on pathogenic properties again if subjected to certain conditions or sown upon proper soil? A definite answer to this cannot be given at the present time. Many bacteriologists have succeeded in diminishing the virulence of the true bacillus, so that it seems proved that the so-called pseudo-bacillus may be derived from the virulent form by placing it under conditions unfavorable for its development, such, for instance, as exposure to light. It is not so well established, however, that the virulent form may be derived from the pseudo-bacillus, although ROUX and YERSIN have augmented the virulence of the latter by inoculating guinea-pigs with it and at the same time with a streptococcus. Although neither microörganism alone could produce death, the two in conjunction proved fatal. Other microörganisms whose pathogenic properties have been lost by culture outside of the body may be restored to virulence by being passed through the body of susceptible animals. Until this question is definitely settled all cases with membrane in which the Klebs-Loeffler bacillus is found should be isolated. Observing clinicians have noticed that unquestionable diphtheria not uncommonly makes its appearance in families in which other members have been suffering with what was supposed to have been follicular tonsillitis, herpetic pharyngitis, or simple angina.

Recently quite a number of cases of sore-throat in which no membrane could be discovered have been investigated by different observers, who have

found virulent Klebs-Loeffler bacilli present, and there can be no doubt that these cases, though they themselves never present the clinical picture of diphtheria, may transmit the disease to susceptible persons. Such cases are, of course, more common in those constantly exposed to diphtheria.

Another important fact that has only recently been given prominence is that the true bacillus diphtheriæ or the pseudo-diphtheria-bacillus may be present in association with other acute infections. It has been thought that different infections could not exist in an individual at the same time, and that the throat-conditions of such diseases as scarlet fever, typhoid fever, and measles were not produced by the same microörganism as is known to cause diphtheria.

In the great majority of cases of scarlet fever the sore-throat is caused by cocci, either streptococci or staphylccocci, alone or associated, and yet in quite a large number of cases the bacillus diphtheriæ is present, as a rule in association with cocci, but in exceptional cases alone. The proportion of such cases is ordinarily not large, although MORSE found the Klebs Loeffler bacillus present in the throat in twenty-three of ninety-nine cases of scarlet fever examined in the Boston City Hospital.

The sore-throat of measles is usually caused by cocci, and yet the Klebs-Loeffler bacillus has frequently been found present; while in typhoid fever complicated by the presence of false membrane in the pharynx this microörganism has been found present in a very large proportion of the cases examined bacteriologically. As COUNCILMAN has stated, perhaps pseudo-membranous inflammations of the throat in the course of typhoid fever are frequently overlooked because of the hebetude of the patient.

In follicular tonsillitis quite a variety of bacteria have been found, but there can be no doubt that diphtheria frequently coexists with this affection.

Of course, in all of these states the throat-condition may not have been primarily caused by the Klebs-Loeffler bacillus, but the soil being rendered favorable, secondary infection has occurred. At any rate, as KOPLIK concludes, *we should regard all specks on the tonsils as suspicious, and if not diphtheric, at least liable to become so.*

When the wide distribution of the bacillus diphtheriæ, in either its virulent or its attenuated form, is considered, as well as the impossibility in many cases of determining clinically the nature of membranous throat-affections, the importance of systematic bacteriologic examination in all doubtful or suspicious cases must be obvious.

The example of the Health-Board of New York City in providing for bacteriologic examination in all suspicious cases were well followed by all large cities. Sterilized tubes containing cotton swabs can be obtained by any practising physician from any of numerous depots distributed over the city. With this material blood-serum tubes are inoculated, and in twenty-four hours a positive conclusion can be reached as to the presence or absence of the Klebs-Loeffler bacillus. Of the first 2000 cases examined in this way by the New York Health-Board 1442 were instances of true diphtheria, while 433 were examples of pseudo-diphtheria.

These figures indicate the amount of good to be realized from such a plan of systematic examination. It is perhaps no exaggeration to say that far more harm comes from the spread of diphtheria through mild cases, either not recognized or not reported and not isolated, than from the very malignant cases, for of these latter there is a popular fear, and they are summarily dealt with. It would, therefore, appear that health-boards could do far more good by instituting some means by which an accurate diagnosis could be made at once, and suitable measures in accordance therewith promptly adopted, than by detailing one or more men to watch a house harboring a malignant case of diphtheria, or by sprinkling carbolic acid in the back-yard and cellar of a house in which a case of ordinary severity develops.

Yet another point demands attention, viz., the time, after all membrane disappears, at which isolation may cease. In the light of recent investigations there is perhaps much harm done in this direction, for the bacillus diphtheriæ has been found in the pharynx and nasal cavity in cases of diphtheria a much longer time after the membrane has disappeared than isolation is usually enforced. In a series of cases examination would perhaps show that the Klebs-Loeffler bacilli are present in the nasopharynx on an average from ten to fifteen days after the membrane has disappeared, but it must be remembered that in individual cases they may persist for five weeks, and in a case mentioned by WILLIAMS they were present eight weeks after the disease had come to an end. The bacilli found after the disappearance of the membrane are not the pseudo-bacilli, but possess active virulence, as has been shown by the inoculation of guinea-pigs. The length of time that these bacilli persist after an attack of diphtheria

seems to bear no relation to the severity of the disease, but it does seem to be longer in cases in which there is some chronic disturbance in the naso-pharynx, while it is shorter in cases in which antiseptic sprays are long employed.

Isolation is certainly very often not continued long enough in private practice, while it has been found by Tobieson that of a series of forty-six cases discharged from a hospital as cured, culture showed the presence of the Klebs-Loeffler bacillus in twenty-four.

The rule adopted by the New York Health-Board could be followed with advantage by other boards, *i. e.*, that no case can be considered free from the danger of spreading the contagion until culture has demonstrated the absence of the Klebs-Loeffler bacilli.

EDITORIAL COMMENT.

Facilis est Descensus.—A correspondent has called our attention to a reprint from the *Journal of the American Medical Association* upon "The Treatment of Typhoid Fever," accompanied by a circular-letter, with both of which we have also been favored. If our readers will recall the circumstances under which the original publication of the article reprinted was made, the criticism it then elicited, the extraordinary journalistic departure and the ordinary abusiveness with which that criticism was met by *The Journal of the American Medical Association*, and the fact that the author was at San Francisco deemed worthy to be elected one of the trustees of The American Medical Association; if they will then for a moment consider the attitude of the said trustees toward outright nostrum-advertising, they will see that on the matter under consideration, which can hardly be designated one of outright nostrum-advertising, comment on our part would be as useless as it is superfluous. We, therefore, simply cite the title of the reprint and reproduce the circular with which we have been favored, leaving the members of the profession to form their own judgment.

"Can Typhoid Fever be Aborted? Read before the Mississippi Valley Medical Association, October, 1893. By J. E. Woodbridge, M.D., Youngstown, O. Reprinted from *The Journal of the American Medical Association*, February 10, 1894. Chicago: Printed at the office of the *Journal of the Association*, 1894.

"My dear Doctor: I have made especial arrangements for the reception at the Youngstown City Hospital of all cases of typhoid and malarial fever, where, if sent for my treatment, they will receive the best possible care and nursing; and, as by the treatment I have advised there is never any danger of intestinal lesions, there can be no objection to moving these cases any distance.

"May I invite your attention to the enclosed reprint of the first part of my paper, written for the Mississippi Valley Medical Association, the second part of which, giving treatment, will be sent if you wish it.

"Fraternally yours,

"John Eliot Woodbridge."

"Youngstown, O., August 13, 1894."

REVIEWS.

A Text-book on Diseases of the Eye. By Henry D. Noyes, A.M., M.D. Second revised edition; 816 pages, illustrated. New York: William Wood & Company, 1894.

Concerning this second edition the author says: "In revising this treatise numerous additions have been made to render it more complete. For example, those parts of cerebral anatomy and pathology which have a bearing upon the eye have been discussed at unusual length for such a work; this is true both for the motor nerves and for the optic nerves. Some chapters have been considerably modified and some have been rewritten; for example, those on granular conjunctivitis, asthenopia, sympathetic ophthalmia, glaucoma, cataract, hemianopsia, etc."

The selection of thin paper permits a desired reduction in the size of this volume. The illustrations on the whole are good, but the proof-reader has been careless at times, as for instance in "*atrophia*," p. 68; plate III, instead of A, p. 651.

Exceptions may be taken to certain statements in the chapter on refraction: Gr. x of homatropin to ℥j, instead of gr. xx, have in conjunction with cocain been found a very competent substitute for atropin by so many skilful ophthalmologists that the indications for its use should have passed the line of uncertainty in a new edition of a text-book. Likewise will a careful study of many thousand cases convince the investigator that perhaps one-half, if not more, have refractive errors less than 1 D., especially in astigmatism, and if the ophthalmometer and ophthalmoscope can claim only an accuracy of 1 D. within the true state of refraction, the question naturally arises: Why use these instruments if you have to rely, after all, upon the test-glasses? And if so, why not say so?

Careful refractionists will also disagree with the author's statement that the use of a mydriatic is rarely necessary in myopic astigmatism, but will insist that it should be employed in all refraction-work, at least up to the age of presbyopia, if good results are to be obtained.

It hardly becomes an author of Dr. Noyes' standing to ignore the much-discussed and often-contradicted question of "graduated tenotomy" with the simple statement of "I have had no experience with it." The author of a text-book should not pass over one of the leading questions of the day in such an indefinite manner, but should at least present the arguments and facts in such a way that the student can form some kind of opinion about the usefulness of the operation, and not beg the question by quietly ignoring it.

Objections will also be made by many to the advice as to wearing prisms constantly for moderate degrees of muscular error. While probably few will deny their usefulness, it should not be forgotten that they rarely, if ever, cure the existing evil, while gymnastic prism-exercises not only do away with the wearing of the prisms, but positively, and, as far as experience can demonstrate, *permanently cure* not only moderate, but quite large insufficiencies of the interni.

The chapters on diseases of and operations on the eye are written and illustrated in a clear and concise

manner, and the author's large experience shows all through this portion of the work.

A well-selected bibliography of useful literature on the eye and a carefully compiled index close a book which will prove not only an excellent text-book for students of ophthalmology but also a convenient reference-book for the general physician.

Biography of Eminent American Physicians and Surgeons. With Many Portraits. Edited by R. French Stone, M.D. Indianapolis: Carlin & Hollenbeck, 1894.

This is a work involving great expenditure of time, money, and industry. It consists of biographic sketches of living and dead physicians, in many cases illustrated with portraits, and in some cases with autographs. There is a general index, and a classified index under city names, giving the residence and line of practice of the living among the subjects of the sketches. How volumes of this kind are prepared, and what is the *quid pro quo*, not in the case of all, but in the case of 90 per cent., of the persons mentioned, is an open secret. The opinions of good men differ as to whether or not the practice is worthy. We have been interested in comparing the teaching list of Philadelphia colleges with the index of this volume, and the suggestiveness of the omissions of names of dead and living teachers thus discovered is very great. We give a partial list herewith: A. C. Abbott, Roberts Bartholow, J. Solis-Cohen, John C. Da Costa, W. S. Forbes, S. W. Gross, F. P. Henry, Henry Leffmann, Clara Marshall, William F. Norris, Charles A. Oliver, William H. Parish, John B. Roberts, J. H. C. Simes, J. Madison Taylor, James B. Walker.

The average of eminence of these teachers and authors is certainly not below that of the average "eminent physician and surgeon" mentioned in the work. It is an entertaining matter to distinguish between the articles in preparing which the subjects have had no part and those which are autobiographic in origin if not in form. Among the latter it is also interesting to observe the relative extent to which different men have "written themselves up." Thus the editor disposes of Dr. Osler in some twenty lines, while many a man whose name is unknown to us, and probably to nine-tenths of the medical world, takes two columns or more to describe in glowing terms his personal qualities, enlarge upon his wife's pedigree, give long lists of the distinguished professors and tutors whose instruction he has enjoyed, and catalogue every insignificant paper he has read at society meetings or inflicted on the journal-reading public.

Notwithstanding all this, the book contains much valuable and interesting information, and we trust the sale will be sufficiently great to compensate the editor for the time, labor, and money he has expended in its preparation.

A System of Legal Medicine. By Allan McLane Hamilton, M.D., and Lawrence Godkin, Esq., assisted by numerous Collaborators. Vol. I, 657 pages. New York: E. B. Treat & Co., 1894.

It is apparently nowhere definitely stated in this volume as to how many volumes this system is to comprise, but even if only an additional one is to be issued the work will be an extended manual of medical jurisprudence. There will soon be no lack of guidance in this field, for several "systems" are in course of publication. In the present work American contributors are exclusively engaged, except that incidental to the chapter on "Death in its Medico-legal Aspects" Dr. F. A. Harris has availed himself of the notes by a London physician of examination of mutilated remains found in various parts of that city. These are noted in the preface as the Whitechapel cases, but with one exception they do not seem to be the cases that made "Jack the Ripper" notorious some years ago. There is, indeed, in modern treatises on medical jurisprudence a tendency to excessive multiplication of illustrative cases and to full descriptions of them. This method makes interesting reading, for the records of this department are highly dramatic, but the tendency ought to be curbed.

The present volume contains numerous woodcuts and several color-plates. Among the latter is to be especially noted the frontispiece, a representation of the mucous surface of the stomach of a child poisoned by arsenous oxid. The plate representing the color-tests of some of the common alkaloids is an interesting example of perverted ingenuity. These colors can be easily obtained for comparison and study by the chemist, and why the publisher should be put to the expense of such unnecessary illustration is past guessing. Plates of color-reactions of rare bodies or of typical appearances that cannot be produced at will are, of course, valuable, but the intelligent chemist who wants to study the color-reactions of strychnin will do so with the materials themselves and not by examining these plates.

Among the specially interesting articles are those on "Ptomaïns" and on "Indecent Assault on Children." The former article is contributed by Dr. Vaughan, and the latter by Dr. Gibbs, examining physician to the New York Society for the Prevention of Cruelty to Children.

The illustrative cases in all parts of the volume are largely American, and serve to show how rapidly the larger cities in this country are approaching the degraded moral and physical state of the European capitals.

The typography is good, and there is a commendable absence of italics, displayed titles, and confusing subdivisions.

Tratato Elemental y Practico de Patologia y Cirugia Ginecologicas. Por M. M. Ponte. Primero volúmen. 8vo, pp. 475. Curazoa: A. Bethencourt & Son, 1891.

Gynecologic works in Spanish are a rarity, and this one from the pen of a Caracas practitioner, engaged as a specialist, is a novelty from Central America, which as yet has contributed but little to medical science. Dr. Ponte dedicates his work to Dr. Jules Péan, of Paris, well known in the field of gynecologic surgery, and according to his preface, must have completed his first volume in August, 1891, or nearly three years ago. His bibliographic list includes 201 names of authors consulted in preparing the volume, many of them well-known writers in French, German, Italian and English; among the last being the six Americans, Battey, Bozeman, Emmet, T. G. Thomas, Goodell, and Levis. Several Caracas physicians have been educated in Phila-

delphia; but among the young men of Spanish America, French is so generally learned that they naturally go to France for a medical education and degree, and are therefore most familiar with French medical ideas and progress. Cuban young men quite commonly learn both French and English, and hence are likely to study in the United States, where there are many from their own country engaged in business; but men of Spanish blood are not given to writing medical books, although they do contribute to their own journals; Spain is much behind Italy in original medical thought and practice.

This work of Dr. Ponte was prepared after a gynecologic experience of twenty-five years. It is purely elementary; treats of a large number of female diseases systematically and briefly, and presents no illustrations of any kind. Two hundred and fifty-nine pages are devoted to a study of the vulva and its diseases, including defects of development, hermaphrodism and dermatology; these constitute Part I. Part II treats of the vagina, and covers sixty pages; and Part III of the urethra, in fifty-five pages. The first part treats of forty-eight diseases and their varieties, located in the vulva. These are not illustrated by cases, and we are left in the dark as to their respective prevalence in Venezuela. This volume is mainly a compilation, and its author lays no claim to originality; the second may be of quite a different character.

Climates of the United States: in Colors. By Charles Denison, A.M., M.D. Being a popular edition of Denison's Charts. Chicago: The W. T. Keener Company, 1893.

Like many tables of medical statistics, the stereotyped meteorologic records which are invoked and quoted by the interested advocates of every sort of climate under the sun are usually worse than worthless; they are delusive. Actual climates refuse to be mapped and labelled. These conventional weather-records are looked upon by travel-wise people much as the veteran practitioner looks upon the crisp diploma of the just-hatched graduate: "From this document, young man, I assume that you intend to become a doctor."

An intelligent digest of the facts supplied by the Weather Bureau furnishes a plausible basis from which to deduce the leading characteristics of a given climate, even when actual residence discloses specially favorable or unfavorable characteristics which are utterly inexplicable from the recorded data. Climatography may, therefore, be said to bear about the same relation to the real characteristics of any locality that geography bears to the actual, verdure-clad landscapes and esthetic perspective of a country. Nevertheless, weather-records are as indispensable to the student of climates as maps to the traveller; and while Dr. Denison does not claim to have done as much for his pet subject as Mercator did for geography, he has added considerably to our facilities for studying and comparing local climatic conditions in the United States, and deserves the thanks not only of the profession but of the community, for arranging and presenting in a readily accessible form such salient facts concerning the climatology of this country as can be embodied in diagrams, colored charts, and apt compilations of accumulating statistics.

The work is issued in a style both convenient for the reader and creditable to the publishers.

Congenital Affections of the Heart. By George Carpenter, M.D. Lond. 8vo, pp. 103. London: John Bale & Sons, 1894.

For a proper conception of congenital affections of the heart, a knowledge of the various phases of development through which this viscus and its great vascular trunks pass is primarily essential, as many of such lesions are due directly or secondarily to abnormalities of development. It would be interesting (if the point could be determined) to know in what proportion of cases, if in any, defects of development occur independently of palpable exciting causes, such as inflammatory conditions, mechanical influences, traumatism, and the like. This thought is suggested by a perusal of the little book before us, in which is described the mechanism of the various morbid conditions of the heart and great vessels found at birth. The etiologic factors are briefly discussed, the symptomatology at greater length; the diagnosis, with its difficulties, is duly considered; the factors upon which the prognosis is based are indicated; the measures to be adopted in treatment are pointed out. The work, while not elaborate and discursive, presents in a simple manner the essential facts concerning a somewhat neglected subject.

The Care and Feeding of Children. By L. Emmett Holt, M.D., Professor of Diseases of Children in the New York Polyclinic; Attending Physician to the Babies' Hospital and the Nursery and Child's Hospital, New York. New York: D. Appleton & Co., 1894.

This neatly-bound and well-printed little book of sixty-two pages has been written for the use of mothers and nurses who have the care of children. The question-and-answer method has been followed, and everything has been sacrificed to clearness and simplicity. The book contains such knowledge as should be acquired by every nurse and mother, and is admirably adapted to fill the place for which it is intended.

Weekly Abstracts of Sanitary Reports Issued by the Supervising Surgeon-General, M.-H. S. Vol. VIII, Nos. 1 to 52. Washington: Government Printing-office.

This volume of thirteen hundred pages and index contains a large amount of statistics and other materials of sanitary interest, issued in weekly bulletins during the year 1893. It is impossible to give a summary of its contents, but we may note the text of the U. S. Quarantine Act, accounts of methods of disinfection and inspection at various foreign and domestic ports, and tables of mortality in the principal cities of the world. A feature of interest is the low death-rate from enteric fever in most of the cities of Europe.

Essentials of Physics. By Frederick J. Brockaway, M.D. Second edition. Pp. 318 and index. Philadelphia: W. B. Saunders.

This book is arranged on the question-and-answer system, though it seems from the brevity of the questions

and the fulness of the answers that the author is not much of a believer in the plan. There can be but little doubt that whatever disadvantages attach to condensed manuals for the use of students, the system of questions and answers is the most objectionable method. In this manual the questions amount to little more than substitutes for side-headings, and the answers frequently extend into accessory fields.

The present edition has been prepared with the assistance of some recently-issued works on physics. It is a good summary of this department of science.

VITAL STATISTICS OF THE DISTRICT OF COLUMBIA AND BALTIMORE, COVERING A PERIOD OF SIX YEARS, ENDING MAY 31, 1890. BULLETIN OF CENSUS OFFICE. BY JOHN S. BILLINGS, M.D. Government Printing-office.

ALTHOUGH consisting largely of mortality-tables, this bulletin deserves notice, because it presents a careful study of the distribution of causes of death in Baltimore and Washington by sanitary districts, a method that is much superior to classification by wards. Wards have usually merely political boundaries and ought to be disregarded in sanitary reports. Many maps of uniform scale are introduced, showing proportional prevalence of important diseases.

CORRESPONDENCE.

THE MEETINGS OF THE COLLEGE OF PHYSICIANS.

To the Editor of THE MEDICAL NEWS,

SIR: Noticing in THE MEDICAL NEWS a list of society-meetings, in which those of the College of Physicians are mentioned, I beg to state for the information of the readers of THE NEWS the conditions upon which visitors are received at meetings of the College or of its Sections.

1. Meetings of the College. "At the stated meetings, except during the consideration of the private business of the College, strangers may be present *on the invitation of a Fellow, who shall present them to the President* and shall be held responsible for the character and professional standing of the persons introduced by him."—*Ordinances and By-laws, Chapter IV, Section 4.*

2. Meetings of Sections. "No person not a Fellow of the College shall attend any meeting of a Section except by *specific invitation to that meeting by a Fellow, who shall give the name of the visitor to the Clerk of the Section* and be responsible for the visitor's actions at the meeting. No person not a Fellow shall take part in any discussion at a Section meeting, except on invitation of the President or Chairman."—*Standing Rules for Sections, Section 6.*

Yours respectfully,

CHARLES W. DULLES, *Secretary.*

NEWS ITEMS.

The British Medical Association will hold its sixty-third annual meeting in London July 30 and 31 and August 1 and 2, 1895, under the presidency of Dr. Russell Reynolds.

Cholera.—It is reported that twenty-one cases of cholera occurred at Marseilles between August 4th and 20th. About two hundred fresh cases of cholera are reported daily in Galicia. The mortality exceeds fifty per cent.

A Pasteur Institute in Vienna has been established for the treatment of cases of hydrophobia by the method of inoculation of Pasteur.

BOOKS AND PAMPHLETS RECEIVED.

Enterorrhaphy; its History, Technique, and Present Status. By N. Senn, M.D., Ph.D., LL.D. Reprinted from the Journal of the American Medical Association, 1893.

A Manual of Minor Surgery and Bandaging, for the Use of House-Surgeons, Dressers, and Junior Practitioners. By Christopher Heath, F.R.C.S. Tenth edition. Philadelphia: P. Blakiston, Son & Co., 1894.

A Case of Suprapubic Cystotomy in which the Bladder was Distended with Air Instead of Water, and Four Hundred and Ninety-five Calculi Removed. By W. W. Keen, M.D. Reprinted from the Journal of Surgery, Gynecology, and Obstetrics, 1893.

Relation between Diseases of the Upper Air-passages and Diseases of the Eye. By J. G. Carpenter, M.D. Reprinted from the University Medical Magazine, 1893.

The Mechanical Treatment of Osteitis of the Knee. By Henry Ling Taylor, M.D. Reprinted from the New York Medical Journal, 1893.

Fourth Annual Report of the College Settlements Association. From September 1, 1892, to September 1, 1893. Philadelphia: Avil Printing and Lithographing Co., 1894.

A Study of Dietaries. Partial Report of Dutton Fellow, College Settlements Association, 1892–93. By Amelia Shapleigh. Pamphlet.

The Subjective Value of a Social Settlement. By Jane Addams. Reprinted from the Forum, for November, 1892.

A Contribution to Our Knowledge of Epidemic Cerebro-spinal Meningitis. By Simon Flexner, M.D., and Lewellys F. Barker, M.B. Reprinted from the American Journal of the Medical Sciences, 1894.

Gangrene of the Scrotum. By Charles W. Allen, M.D. Reprinted from the Journal of Cutaneous and Genito-Urinary Diseases, 1894.

Opium as an Hypnotic in Old Age. By J. Y. Dale, M.D. Reprinted from the University Medical Magazine, 1894.

The Annual Report of the Superintendent and Physician of Walnut Lodge Hospital, Hartford, Conn., at the Annual Meeting, January 3, 1894. Hartford, Conn.: Press of Case, Lockwood & Brainard Co., 1894.

Total Extirpation of the Uterus. Cases Illustrating Various Indications for and Different Methods of Performing the Operation. Remarks upon Removal of the Uterus in Diseases of the Appendages. By George M. Edebohls, A.M., M.D. Reprinted from the Transactions of the New York Obstetrical Society, 1892.

The Technique of Total Extirpation of the Fibromatous Uterus. By George M. Edebohls, A.M., M.D. Reprinted from the American Journal of Obstetrics, 1893.

Addresses by the President, Samuel C. Busey, M.D., at the Celebration of the Seventy-fifth Anniversary of the Medical Society of Washington, D. C., and at the Banquet, February 16, 1894. Pamphlet. Washington, D. C.: Gibson Brothers, 1884.

Twenty-sixth Annual Report of the New York Orthopedic Dispensary and Hospital, 1894.

Improved Apparatus for Pott's Disease of the Spine. By Henry Ling Taylor, M.D. Reprinted from the Canada Medical Record, 1893.

ORIGINAL ARTICLES.

THE USE AND ABUSE OF ARSENIC IN THE TREATMENT OF SKIN-DISEASES.[1]

BY ISADORE DYER, PH.B., M.D.,
OF NEW ORLEANS, LA.;
PROFESSOR OF DERMATOLOGY IN THE NEW ORLEANS POLYCLINIC; LECTURER AND CLINICAL INSTRUCTOR ON DISEASES OF THE SKIN, MEDICAL DEPARTMENT, TULANE UNIVERSITY; DERMATOLOGIST TO THE CHARITY HOSPITAL; CONSULTING DERMATOLOGIST TO THE EYE, EAR, NOSE, AND THROAT HOSPITAL, ETC.

WHEN Erasmus Wilson so strongly advocated the usefulness of arsenic in the treatment of skin-diseases, without discriminating closely, and only qualified his indorsement with the caution to be employed in its use, he but voiced the enthusiasm which at that time had placed arsenic upon the pedestal that it still tends to occupy. At the time of Biett, Wilson, Cazenave, Schedel, Behrend, and others, the general practitioner had scarcely escaped from the simple classification of skin-diseases into eczema, scrofula, and syphilis, with an occasional inspired diagnosis of psoriasis, herpes, or the like. It is hardly to be wondered at, then, that the general practitioner should welcome a remedy that had found favor with the dermatologists of the time in the very diseases under whose shelter he had found a refuge-diagnosis. Cazenave did not qualify his adjectives when he wrote of arsenic as an heroic remedy, meaning not radical but supreme. Almost every good thing in medicine has found its abuse in its early recognition, and soon a rational measure is made the excuse for enthusiastic excess, and the true value of a remedy is hidden by its indiscriminate usage.

Arsenic has drifted from its essential usefulness, and has become to a multitude of routine practitioners a panacea for all cutaneous affections. At the slightest intimation of a disturbance of the skin there is an echoing response in the physician's mental *vade mecum* of arsenic. In its various shapes and combinations, arsenic is administered for a variety of skin-affections, many of which could in no rational way be influenced by the drug. I have seen typical cases of the parasitic diseases of the skin, even the itch, treated for a long period with arsenic, as if painting the cellar would patch the roof.

[1] Read before the Texas State Medical Association, at Austin, April 25, 1894.

The reaction has come, and it is a rational one at that. Instead of being employed to meet all possible and impossible indications, arsenic can be relegated to specific usefulness in therapeutic measures, and permits only of exceptional variations from its proper sphere. After long study and investigation, Dr. Fox, of New York, in collaboration with other dermatologists in this country, arrived at the conclusion that arsenic was not only of no service in some of the diseases in which it is often administered, but that it did positive harm, not only in the production of additonal trouble in the skin, but by preventing the use of other and better remedies. Moreover, these investigations elucidated the fact that there was no series of cases in which arsenic could be said alone to have produced a cure.

With this kernel of sound meat for our consideration, I feel that a logical discussion of the uses first, then the action and abuses of arsenic, will, in some small measure, carry a germ of the reaction to those of you who have a penchant for arsenic-administration, without knowing just why.

The action of arsenic is twofold—local and general. Topically applied, its action is first of all stimulant and irritant; and if sufficiently brought in contact with the surface it is caustic. Generally, arsenic is a nerve-tonic, acting on the vasomotor centers, and decidedly affects the peripheral nerve-terminations. Its action on the spinal cord is irritant, and an overdose is evidenced by a widespread multiple neuritis.[1] The evidence indicates that small doses check tissue-change and decrease nitrogenous elimination, while large, toxic doses have the opposite effect. Arsenic is a direct stimulant to nutrition. It is alterative.

Upon the skin, the effect of ingested arsenic is much the same as that of the drug when used locally.[2] There may result inflammatory redness, vesicles, pustules, etc., a sensation of heat, burning, pain, and there may be exfoliation of the epidermis in large flakes.

Arsenic is selective of diseased tissue, picking it out and acting on it.[3] The drug is known to exercise its influence almost exclusively upon the epithelium of the skin. Its chief action here is upon the mucous layer of the epidermis. It has a similar action upon the mucous membranes, viz., increasing

the hyperemia. At first stimulant to the cell-forming elements of the rete, arsenic soon causes such a degree of overwork that the power of cell-production is finally lost, or, as Jamieson[1] well expresses it, it induces in them a premature old age.

In those skin-diseases, then, in which an alterative action is demanded, arsenic is of service. Its stimulant action is indicated when there is a stagnation of the cell-forming element in the rete, or when this element is depressed by a chronic inflammatory process. Just how long and just how far this stimulation can be kept up must be judged from the degree of activity of the cell-production.

Arsenic must find some usefulness in the diseases of the skin of vasomotor origin, whether acute or chronic, and this point should be determined before the drug is advocated or condemned. In deep-seated lesions of the skin, from what we have seen, arsenic is not indicated, and if used, the result would be questionable. Because of the tendency to produce hyperemia, arsenic ought not to be given in acutely inflammatory conditions, which the drug must necessarily make worse. On just the same account it is contra-indicated in the pruritic diseases, because, in itching, the chief underlying condition is hyperesthesia, whether in its common signification of an excessive irritability of the sensory nerves, or in the sense of an excess of an engorgement of sensation.[2] The attendant irritation and subsequent hyperemia make itching persistent, and arsenic would only add to the production of the agony.

It is becoming more and more the practice of dermatologists to treat cutaneous diseases according to their pathology. Subjective symptoms, of course, are met, as in other diseases, but the etiology is investigated, and the treatment based on a pathologic plane.

In the parasitic diseases, the most effective antagonist to the special parasite is selected for use; in the pustular, or the coccogenous diseases, as Hyde has recently called them, antiseptic measures are employed locally, while, internally, anti-pyogenic remedial agents are administered. When there is an acute inflammatory condition in or on the skin, the points of attack, both locally and internally, are through the reduction of the inflammation.

The diseases for which arsenic seems to be especially useful are few. At the top of the list stands psoriasis, then chronic eczemas, and the lichens, with some of the hydroa.

With many dermatologists arsenic is preëminently the essential treatment of psoriasis. According to Brocq, Vidal used arsenic for a long time, to the exclusion of other medication. He administered the drug in large doses for a long period of time, and at the cost of systemic intoxication. In recommending arsenic in chronic psoriasis, Brocq apologizes for its accidents, and warns the physicians to guard against the possible inconveniences of treatment.[1] Pye-Smith commends the use of arsenic in psoriasis, but suggests that it be carried to tolerance, then the dose dropped to the original small dose, and the same method of administration resumed. Duhring says that arsenic is unquestionably of great value in psoriasis, but should be withheld until the disease is settled in its course. Weyl[2] and Anderson,[3] on the other hand, state that the more recent the eruption, the more readily, as a rule, psoriasis yields to arsenic, while chronic and relapsing cases are more rebellious.

It is noticeable that arsenic is of service in some cases of psoriasis, while in others the results are negative. While the etiology of psoriasis is still *sub judice,* and the neuropathic vies with the parasitic and the syphilitic element as causative factors, it is difficult to determine what the reason should be for the discrepancies in the effect of treatment. It must be remembered, however, that psoriasis is a self-limited disease, tending to get well of itself. It recurs periodically and has seasons of recurrence, be it winter or summer, spring or fall. Some cases get well in spite of all treatment, and it is questionable if arsenic plays any particular part in the cure. Few cases of psoriasis are treated internally alone, and the external treatment may deserve the credit. Granting, however, that arsenic is capable of removing the disease in given cases, and fails in others, it must act in the first instance, if the therapy of the drug as acknowledged is correct, through its effect upon the peripheral nervous system first, or by its direct local presence. Its failure to act in one of two apparently parallel cases would indicate that this nervous element was lacking in the case that failed to respond to arsenic.

The pathology of psoriasis gives evidence of cell-exudation and cell-proliferation. There is moderate inflammation, with increased development of the layers of the rete. There is involvement of the papillæ of the corium, and a consequent and enormous increase in the horny cells of the epidermis, from the rapid proliferation of aborted cells from the mucous layer. Auspitz[4] contends that psoriasis is not inflammatory, but due to an anomaly of the process of cornification, or the keratinization of the epithelial cells. The etiology of psoriasis is unknown, the pathology still in some question, and the treatment thoroughly empirical. Arsenic occu-

pies a strong place in the list of remedial agents, and seems to act in overcoming the cell-aborting process of the rete by stimulating a healthy activity, while the general tone of the skin is raised through the stimulating effect of the arsenic upon the peripheral nerve-plexuses and the nerve-endings themselves.

The term lichen really includes but two types of a chronic inflammatory eruption consisting of papules. In lichen ruber acuminatus the papules are conical and tend to coalesce. In lichen ruber planus they are flat, square, angular, and vary in color from pink to violet, although sometimes white. The essential pathologic process in both types begins in the corium. In lichen acuminatus the process is chronic and inflammatory, beginning in and around the hair-follicles, with a consequent enlargement of the sheaths of the follicles through a marked cell-development.[1] In lichen planus the process begins around a sweat-gland, usually in the upper part of the corium, resulting in a subsequent thickening of the rete and enlargement of the papillæ by a down-growth of the inter-papillary processes. The etiology of both, like that of psoriasis, is still an open question. That the distribution is suggestive of a nervous origin, and the itching (paroxysmal in type) suggests a nerve-hyperemia is about all there is in evidence. The indications for treatment are similar to those in psoriasis. In the lichens, however, the general health is profoundly influenced and nervous symptoms are present, notably nervous exhaustion, hysteria, and the like. Arsenic fails here, as in psoriasis, in many cases. In chronic cases the drug is certainly useful. It must act in hastening the shedding of the excessive cell-proliferation by controlling the nerve-terminals.

Chronic eczemas and eczemas of reflex nervous origin form another group of diseases treated by arsenic. It should go without saying that in the acute types of eczema, in which there is edema, infiltration, vesicles, redness, and itching, all evidences of an acute catarrhal condition, arsenic is absolutely contra-indicated. When this condition has thoroughly subsided, leaving behind a marked cellular deposit, with enough swelling, redness, itching, and scaling to determine its eczematous nature, then arsenic may be of service. Stimulation is the essential of the treatment, and by reawakening the dormant cells of the rete, already on their way to connective-tissue degeneration, arsenic finds its usefulness.

Pemphigus and the tropho-neurotic diseases, with bullous eruptions, are favorably affected by arsenic. Nervous lesions are often found associated with pemphigus. These may be either vasomotor or tropho-neurotic; in either case constituting an indication for the administration of arsenic, one of whose properties is an influence upon the vasomotor center.

Dermatitis herpetiformis belongs to the same group as pemphigus, being associated, according to Elliot, Duhring, and others, with some reflex neurotic causation. Shock, grief, anxiety, overwork, pregnancy, and the climacteric in women, are among the important factors. Crocker classes dermatitis herpetiformis with hydroa, although the eruption is varied in type, and presents lesions of papular and urticarial tendency, but more commonly characteristic bullæ. Most observers accept the neurotic factor in the etiology and confess the uncertainty of the pathology. The distribution and the resemblance to the eruptions of pemphigus, with the pronounced symptoms of nervous lesions, evidenced by a variety of manifestations, depression, melancholia not uncommonly, and the tendency to recur under conditions of nervous strain, all point to the neurotic factor. On these grounds, arsenic is given, and is found useful in many cases.

The diseases named form only a small part of a long list of cutaneous affections, but include those conditions which, from a rational standpoint, should yield to the accepted therapy of arsenic. They are but a fraction of the diseases for which arsenic is prescribed.

We have seen that arsenic is positively contra-indicated in acutely inflammatory diseases, excepting those of bullous type, distinctly referred to a vasomotor or nervous origin. Arsenic increases the hyperemia of the skin, and in cases of idiosyncrasy, or under prolonged administration, is capable of producing many local disturbances of the skin. Devergie[1] was the first to announce the fact that cutaneous lesions may be caused by the internal administration of arsenic. These skin-manifestations may take the shape of papular, urticarial, vesicular, erysipelatous, and pustular eruptions. To these may be added an erythematous or scarlatiniform eruption.

According to Hutchinson, herpes zoster may be induced by the ingestion of arsenic, and in subjects predisposed to carcinoma arsenic may act as the determining cause.[2] Boils and carbuncles occasionally result.

Among the inconveniences, as Brocq calls them, of arsenic-administration, there is often marked brownish discoloration of the skin occurring on the face and various parts of the body. This occurred in two cases that came under my own observation. In one patient, a psoriatic subject, arsenic has been given for several relapses, and had last been admin-

[1] Crocker, op. cit.

[1] Morrow: Drug-eruptions, p. 70.

[2] Jamieson, op. cit., p. 539.

istered three years before I saw the patient. There were numerous pigmented patches on the extremities, which seemed to have no tendency to disappear. In the second case, one of chronic eczema, Fowler's solution had been given for two months previous to my seeing the patient. There was marked brownish pigmentation in patches over both legs and thighs, which persisted, and was still present six months after the eczema was cured. Only recently Carrier[1] has reported a case of pigmentation of the whole body occurring suddenly during the treatment of a case of psoriasis, and further complicated by warty growths upon the palms and soles, all following the internal use of arsenic. Mathieu[2] has within a month reported a case of chronic arsenical poisoning in which the skin of the patient was bronzed, or slate-colored, in various regions of the body. On the palms and soles, as in Carrier's case, there was marked hyperkeratosis. These discolorations are attributable to the stimulated action of the prickle-cell layer, in which the pigment-cells are found, and, according to some authorities, in which the pigment is said to be formed.

These, then, are some of the chief accidents of arsenic-administration. Notwithstanding these, it is advisable to use the drug in selected cases. But, in the face of these, is it justifiable to carry on a systematic use of the drug in diseases in which the indications are not for it or are positively against it?

Arsenic is popular in the treatment of acne, notwithstanding the fact that the drug has no action on the deep layers of the skin, while acne is essentially a disease due to inflammation of the sebaceous glands or hair-follicles, which are found only in the reticular layer of the corium or in the subcutaneous connective-tissue layer.

Arsenic is often given in the erythemas, both simple and exudative, in spite of the evidence of the presence of acute inflammation in the skin, and marked exudation, which the use of arsenic tends only to increase.

Urticaria is essentially an exudative disease, attended with edema, which is the pathologic origin of the clinical evidence, namely, the wheal. The vasomotor element in the etiology might excuse the administration of arsenic, but the clinical symptoms, with the pathology, would more than counterbalance this. Aside from increasing the exudate, arsenic tends to produce edema, and in overdoses is itself responsible for an urticarial eruption.

Malaria, exposure, and the ingestion of certain medicaments are among the causes of herpes zoster. The direct occasion of the eruption is a peripheral neuritis. How often is arsenic given for this condition, although contra-indicated by its physiologic action, because the drug is a stimulant to the peripheral nerve-endings, and in tonic doses, or given for a long time, it produces this very class of eruption. Nielssen[1] found 10 cases of herpes in 557 cases of psoriasis treated with arsenic, while not one case of herpes occurred in 220 cases treated with potassium iodid.

I have referred to the indiscriminate use of arsenic in parasitic diseases of the skin, which can in no way be affected by the drug. We cannot deny that in some such diseases of the skin arsenic is of undoubted service, but these cases must be selected. Even in those diseases in which there is some specific and rational effect expected from the drug, there is in many instances conspicuous failure. It must be remembered that in many cases of cure attributed to arsenic, some other element in the external or internal treatment may be responsible.

When dermatologists themselves confess that the accidents from arsenic form a large proportion of the drug-dermatoses, and the patient is often afflicted with a permanent souvenir of large and heroic doses of the drug, while the skin-disease aimed at pursues its course not much affected, we should call a halt and question the value of the drug and its indiscriminate use.

We must arrive at the conclusion that instead of being the first, arsenic should be one of the last remedial agents to be used in the treatment of diseases of the skin, and when selected it should only be used in chronic diseases with a general distribution and in diseases associated with a neurotic element.

THE RADICAL CURE OF URETHRAL STRICTURE BY THE RESTORATION OF THE MUCOUS MEMBRANE TO A HEALTHY CONDITION.

BY J. P. BRYSON, M.D.,
PROFESSOR OF GENITO-URINARY SURGERY, ST. LOUIS MEDICAL COLLEGE, WASHINGTON UNIVERSITY.

RECENT advances in our knowledge of the pathogenesis and mechanism of stricture-formation require us to recast, so to speak, our conception of the condition, and at the same time render obsolete or inadequate the definition of certain terms as well as certain classifications once appropriate and sufficient. It is this state of transition that obliges me to ask the indulgence of the Association while I briefly define the meanings which I, at least, attach to certain terms in common use; otherwise I cannot hope to make myself clear. And, first of all, is the definition of the condition we know under the name of stricture. It is plain that we must abandon the mechanical definition which made one of its

[1] Quoted in Crocker, op. cit., p. 207.

symptoms, viz., obstruction, to stand for the disease itself. It is equally plain that a precise definition can only be reached by approaching the problem from a pathologic standpoint.

In a paper reviewing this subject, read by me at the Newport meeting (1889) of this Association, the reasons were given for defining stricture of the urethra to be a chronic contracting peri-urethritis. I have seen as yet no objection raised to this as a pathologic definition. So far as the pathogenesis is concerned, it seems not too much to say that the theory of the leakage of urine or some of the constituents of this complex excretion, through a damaged or absent mucous membrane, for which we are indebted to Mr. Reginald Harrison, is now accepted as the correct interpretation of the process. Such a conception of the nature and etiology of stricture as a surgical disease, placing, as it does, the point of pathologic departure in the urethral mucous membrane, and regarding the subsequent development of the stricture-tissue at the expense both of urethral dilatability and the integrity or even the existence of the normal circum-urethral tissue as dependent altogether upon the lesion of the mucous membrane, both for its inception and its evolution, must of necessity profoundly influence those procedures that aim at its radical cure. Moreover, besides giving new prominence and value to other hitherto little studied features, it enables us to accept a more definite and better classification, and none seems to me more available for our purposes than that of Voillemier, which divides them into inflammatory and cicatricial; the first being lined still with mucous membrane, damaged though it be, the last by none at all, the mucosa having been replaced by cicatricial tissue. Under one or other of these headings any number of subvarieties may be placed, if thought necessary for descriptive purposes.

It is plain, then, that any therapeutic procedure which aims at radical cure of stricture must aim primarily in the one case at a restoration to the normal state of a damaged urethral mucous membrane, and in the other to the replacing of a destroyed portion. Now, whether it be merely coincidence or consequence of this newer conception of the causation and nature of stricture, certain it is that this is just what surgeons of to-day are doing, and in many cases with most flattering success. Warrant for this assertion is found by a reference to the successful cases, observed for a sufficient length of time, of exsection of the strictured areas, followed by suturing of the divided ends, reported by Koenig, of Göttingen, and by Heusner; of exsection of strictured areas, with transplantation of normal mucous membrane, by Wolffler, etc., and the good results attending the immediate and accurate suturing of the divided ends of urethræ severed by traumata, reported by various surgeons. Many such cases are being reported, and there is no question of the soundness of the practice. With what object is this done, unless to obtain a continuous normal, or, as Mr. Harrison would call it, a urine-tight mucous membrane? But it is of inflammatory and not of cicatricial stricture I wish here to speak.

The researches of Oberlander and Neelson have taught us that the inflammatory form of stricture may be expected to follow only upon such a mucous lesion as involves the glands of Littré. Moreover, these authorities have, with others, demonstrated the curability of these lesions by proper topical treatment, especially in the earlier stages, a point long before insisted upon by Otis. Influenced by the results obtained by these observers, and by the teaching of Harrison as to the essential cause, and having for a long time been struck with the rapid and satisfactory disappearance of those hard, fibrous walls surrounding old urinary fistulæ (tissue in every way resembling stricture-tissue), after the urine has ceased to flow over them, I had, as announced in a paper read before the Missouri State Medical Association in April, 1883, been combining topical applications with dilatation, with the view of getting a radical cure if possible in at least some suitable cases. At that time, however, I had not observed any case long enough to be sure of permanence of result, but I have continued the effort, and it is the net outcome of this clinical work that I desire to communicate to-day. Let me say again, that the entire treatment was based upon the theory that, if the mucosa could be restored to a normal state while the stricture-band was undergoing softening and inflammatory involution, we might hope to obtain a radical cure, which would be manifested by failure to recontract after leaving off the use of dilating instruments. Now, it is evident that observation for a number of years is necessary in such cases to justify one in drawing conclusions, and it is equally plain that few patients are so situated as to afford one such opportunities. Thus of fourteen patients upon whom I attempted to practise this method since December, 1887, five only remained under observation after the first year, a time entrely inadequate for the purpose. Of these five, three had linear strictures, and of these three two remained cured after two years' and one-third year's observation, respectively. The third has, though remaining under observation up to the present time, had two fresh gonorrheal infections in sixteen months.

Wishing here to deal only with the question of the influence of local applications made with the intention of restoring to its integrity the damaged mucous membrane lining inflammatory strictures, a proper regard for sources of error would compel us

to throw out of this consideration cases of linear stricture, for it is evident that in this sub-variety only a narrow zone of mucous membrane is in a pathologic state, so narrow that as a matter of fact only diaphragm-like membranes are lifted up, and it is more than probable that carefully practised, simple dilatation will cure this form of stricture without other aid from topical applications. The anatomo-pathologic condition here seems to be a rapid development of the contracting stricture-tissue in and immediately underneath the mucous membrane. Such strictures, though often difficult of penetration with instruments, on account of the eccentricity of their openings, do not often require section, for the reason that only to an inconsiderable extent are the circum-urethral tissues infiltrated with the fibrous, contracting elements. The beneficial influence of pressure upon this narrow zone of damaged urethral membrane is often in itself sufficient to restore it to the normal condition. In this way I think are to be explained many reported cases of cure by all methods of treatment, which methods are found to be entirely inadequate in cases of annular stricture. It is interesting to note in this connection that some of the older surgeons recognized the difference in the curability of these two forms of stricture.

There remain, then, two cases only for present consideration. Of one (No. 6 on my list) but little need be said, as it was apparent from the beginning that the mucous membrane was too extensively damaged to leave any hope of restoration, and the patient only submitted to the treatment in the belief, not encouraged by me, that in some way his wretched condition might be improved. This was a case of extensive inflammatory stricture of almost the entire penile urethra. When the man came under my observation, ten years ago, there were extensive deposits of stricture-tissue around that portion of the urethra extending from the posterior border of the *fossa navicularis* well back into the bulbous sinus. The largest instrument that would pass through all of the strictures was No. 8 F. This condition had followed numerous attacks of gonorrhea, and the stricture had existed for such a length of time that in many portions the fibrous, nodular condition had been reached. Continuous dilatation, interrupted by frequent attacks of urinary fever, brought the duct up to No. 14 F., when under ether internal urethrotomy enabled me to pass a No. 26 F. conical instrument. So indurated were the urethral walls that the duct seemed never to empty itself of urine, and the damaged lining was constantly bathed in this fluid. This caliber was only maintained by repeated introductions of the sound, supplemented by more or less extensive internal urethrotomies, practised during a period of several years. When I first surveyed the urethra with the endoscope I looked upon a mucous membrane which seemed to be pale, atrophied in some places, perfectly smooth, and apparently adherent to the fibrous tissue underneath; in others lined with granulations or wart-like excrescences. On the roof, where I had cut, the tissues seemed to be tucked in, so that a view of the bottom could not be obtained. I was struck with the pale appearance, the apparently bloodless condition of the urethral walls. In a few spots where the stricture-tissue was thickest the mucous membrane seemed to be smoothest and palest. The granulations and warty-covered sections were scraped with cotton on the end of a probe, and to the entire stricture-area a 2 per cent. solution of silver nitrate was applied through the tube, after cleansing. The patient still maintains that these applications have done him good by way of relieving pain on instrumentation, which he performs for himself, and in lessening the tendency to contraction. My own belief is that what of benefit has been derived is to be attributed not to the local applications, but to the long-continued use of the steel sound. The man is now forty-three, has married since he has been under my care, lives a very regular life, and takes excellent care of himself.

In the following case we have an excellent example of the adequacy of this method in a limited number of instances, even excluding linear stricture:

William S., thirty-four years old, married, was first seen February 14, 1885, when the following note was made of his examination: The meatus is narrow (19 F.); there is an annular stricture at the depth of three inches which admits a No. 12 F., and measures one-fifth inch broad; larger bulbs detect the conical shape of the anterior stricture-face. A second stricture in the bulbo membranous part admits only a filiform bougie. The patient has never received any injury to the parts, but attributes his trouble to a gonorrhea which he had sixteen years previously. The examination produced very slight bleeding.

On March 2, 1885, I cut the anterior and divulsed the posterior stricture to 30 F. On March 3, 1885, I visited the patient on account of a slight urethral chill, which came on five hours after the operation. On March 8, 1885, I passed a 30 F. and caused slight bleeding. On March 9, 1885, the patient announced his intention of going South to accept employment. On April 12, 1887, he returned, with both strictures recontracted to their original size; he had neglected the introduction of the sound; had dissipated a good deal; had retention on the previous evening, which had been relieved by Dr. Mayger, who gave a hot bath and opium. I aspirated above the pubis and withdrew fifteen ounces of slightly cloudy undecomposed urine, and tied in a filiform bougie for continuous dilatation.

For six weeks, viz., from April 12 to May 24, 1887, inflammatory dilatation, at first continuous and after-

ward intermittent, brought the urethral caliber up to 31 F. The patient then again ceased to attend. On December 12, 1887, he returned, when an examination showed that the anterior annular stricture had recontracted to 18 F., while the posterior stricture was not discoverable with the bulb admitted by the anterior. Endoscopic examination showed a zone of urethral wall at the site of the anterior stricture, estimated at a little more than a quarter of an inch in breadth, paler than that immediately behind or in front of it; lusterless, with here and there small darker spots, looking like submucous hemorrhages. The mucous membrane fell away from the end of the tube in irregular, transverse, shallow folds. Some minute bloodclots came away on the cotton introduced to wipe off the surface. On the whole the membrane looked paler and thinner than normal. Reintroduction of the instrument to the site of the posterior stricture revealed only a narrow zone, looking redder and more dusky than normal, and slightly velvety. The folds here appeared to be longitudinal. The pallor, so striking within the anterior stricture, was distinctly wanting here. From this time on, intermittent dilatation was practised at intervals of four and six days. Following the withdrawal of the steel sound, applications of 1 and 2 per cent. silver nitrate solutions were made to the stricture-areas.

Within four weeks all visible pathologic appearances at the site of the posterior stricture had disappeared, and the mucous membrane lining the anterior stricture had become redder, smoother, and apparently more supple. At the end of nine weeks the patient discontinued attendance. At this time, though the urethral mucous membrane looked normal, a No. 31 bulb still encountered slight obstruction at the site of the anterior stricture, which was not felt by a No. 30 bulb.

I did not again see this patient until June 13, 1889. Examination on that date showed the urine to be normal, with a slight excess of mucus in that voided in the first over that in the second glass, but containing no pus and no blood. The meatus admitted a No. 33 F. with a little force. A No. 30 F. passed through the hole in the triangular ligament without meeting any obstruction whatever. Endoscopic examination discovered nothing abnormal. No instrument had been passed in the meantime, and the patient observed nothing unnatural. On February 12, 1891, the patient came again to my office, at my request, for examination. Neither the bulb, the blunt steel sound, nor the endoscopic tube disclosed anything abnormal. The patient declared that no instrument had been passed by himself or any person since June 13, 1889.

A brief *résumé* of this case shows that in two years, after thorough cutting and divulsion, an annular and a linear stricture, being neglected and without other treatment, recontracted to their original size, and, on exposure, brought on acute retention, requiring hot baths and opium for its relief. First continuous and then intermittent inflammatory dilatation brought both strictures up to No. 31 F. in six weeks. Neglect of all treatment for six and a half months resulted now in a recontraction of the annular stricture from No. 31 F. to No. 18 F. (13 numbers), with apparently no recontraction of the linear stricture. Intermittent dilatation, combined with topical treatment directed to the restoration of the lining mucous membrane, practised for nine weeks, resulted in a radical cure of the stricture, demonstrated by failure to recontract in the absence of all treatment, and without the introduction of instruments to maintain the caliber, this being proved by observation extending over a space of nearly four years.

The case is an exceptional one for many obvious reasons, chief among which may be mentioned the twice-demonstrated ability for recontraction to take place in the absence of all treatment that would prevent it. The existence of a linear stricture posterior to an annular one is, I think, also exceptional, and there is a possibility that the indications of its existence were deceptive. Certain it is that the posterior stricture seemed to get well on simple dilatation, and promptly. This, however, I believe, is not exceptional in cases of linear stricture, for the reasons already set forth. Of the existence of an annular stricture, at least one-fifth of an inch in breadth, the evidence does not permit me to doubt.

That we will obtain such good results in many cases of inflammatory stricture of the annular variety I do not in the least believe. The whole question of radical cure undoubtedly depends upon our ability to restore to its normal condition the mucous membrane lining such a stricture. That a certain proportion of such strictures can be cured by combining topical treatment with that intended to do away with the purely mechanical manifestations of stricture-disease, I think this case clearly demonstrates. This method of treatment will not, I fear, become very common until patients exhibit more persistence and surgeons less of the prevailing itch for cutting. Less hopeful even than cutting, divulsion, or stretching, would, I think, be electrolysis, which, applied after the manner of the modern schools to a case like this, would be more likely to destroy than to rehabilitate the precious remainder of lining mucous membrane. To this conclusion I think we are irresistibly pushed, knowing as we do that the electrolytic action is chiefly spent upon the surface to which the electrode is directly applied, and we certainly have no evidence whatever of the power of surface-electrolysis to restore damaged mucous membranes in other parts of the body. Why should it be exhibited any more on the surface of the urethral mucous membrane than upon that of any other?

NOTE.—This paper was read before and discussed by the American Association of Genito-Urinary

Surgeons during the Congress of American Physicians and Surgeons, held at Washington, D. C., in 1891. In April, 1893, the patient, William S., again presented himself at my office, and was examined by Dr. H. McC. Johnson and myself. A No. 29 F. blunt steel sound passed without obstruction into the bladder. The urethrometer of Otis, drawn forward after being distended to No. 34 F. in the bulb, had to be gradually reduced to No. 31 F., until it approached to three and one-fifth inches of the meatus, when it could be again distended to No. 33 F. without causing distress. At this distention and position it could be rotated with the application of a little force, but had to be turned down to No. 31 F. before passing forward. In the *fossa navicularis* it could again be distended to No. 33 F. and rotated.

If the evidence of the urethrometer is to be relied upon, it would appear that at the point where the stricture originally was there is now an abnormal dilatation. It is well known that the growth and condensation of the stricture-tissue cause pressure-atrophy of the normal circum-urethral elements, and the inference seems justified that complete atrophy of the stricture-band was not, in this case, followed by their redevelopment. It was a surprise to me to find the urethra so distensible at this point, and yet this is what should have been expected, and it is an additional proof of the permanent cure of the disease. The patient promised to return for an endoscopic examination, but left the city without doing so.

209 N. GARRISON AVENUE.

ORIGINAL ADDRESS.

SYDENHAM.[1]

BY SIR HENRY ACLAND,
REGIUS PROFESSOR OF MEDICINE IN THE UNIVERSITY OF OXFORD.

IT would ill become me to detain you by a full account of the reasons for erecting a statue to Sydenham in Oxford; I might rather be called on to explain why it has not been done before. Suffice it to say that thirty-five years ago the name of Sydenham was written on yonder corbel, between John Hunter and Harvey, so that no other might there be placed. It is a pleasure to remind you that on one of the corbels, orginally suggested by the Prince Consort, some forty years ago, the statue of John Hunter, given by Her Gracious Majesty the Queen, was placed, and that on the next corbel you will unveil to-day the memorial of another great benefactor of mankind, one of an illustrious company of five selected to represent here the science and art of medicine.

On a recent public occasion your Lordship [the Marquis of Salisbury] said of medicine, with your usual force, that "it is the most sober, the most absolute, the most positive of all the sciences." Some not conversant with the facts may dispute this. An art which is based upon physics, chemistry, experimental and observed physiology, the ascertained causation of disease, its prevention as well as relief, not only for the human family, but for domestic animals in every climate, cannot be surpassed in complexity by any art or science whatever. It might seem, therefore, strange that medicine should be represented here by only five persons of all time. But the five are a sixth of the number whose statues can be erected in the court to typify all physical science, ancient and modern. And truly, the five represent a vast range of knowledge and a long history of achievement.

Sydenham, the representative practitioner among the Moderns, stands in the center. On his right is John Hunter, who, for the interpretation of disease, its causes, its prevention, its cure, searched through every form of life in the Book of Nature, existing or extinct, vegetable or animal, from their birth to their death, in their form and development and functions, and through observation, experiment, and treatment, and left a key whereby to unlock the ever-growing wonder of life through death and of death through life. On the other side of Sydenham stands Harvey, to whom it was given to solve the problem that had been unsolved from the remote period since search into the nature of man began. He made it possible to reveal some of the deepest secrets of the higher forms of life through the knowledge of fact and the destruction of unproved speculations concerning the nature of a vital principle.

These three, Hunter, Sydenham, and Harvey built on the foundation of two of the most marvellous men in the marvellous century which produced Aristotle and Hippocrates: Aristotle, the student and first interpreter of the material nature of all animal life, and the analytic and synthetic exponent of the psychic nature of man; Hippocrates, if not actually the founder of medicine as he is sometimes called, yet the first known expositor of the philosophy, the science, and practice of the great art of healing, in some ways unsurpassed even to the present day. These two, in their respective ranges of human observation and deduction, maintained a supremacy over philosophic thought during nearly two thousand years, a supremacy misunderstood and misapplied by their successors.

I may be pardoned, here in Oxford, for saying a few words on the relation of Sydenham to his eminent contemporary, John Locke. It is still a question which influenced most the mind of the other. The epoch of Locke and Sydenham, like that of Aristotle and Hippocrates, was one of the critical periods in the history of thought. Aristotle was naturalist and psychologist. Hippocrates threw his whole force, under the influence of the great minds of antiquity, into the observation and analysis of the diseases of man; their causes, consequences, treatment, and prevention. It is enough to shame the average tone of medical practitioners in the early part of this century that the scientific interest and wide political significance of comparative national health should have been made known in Athens four hundred years before Christ, by the Divine teacher of Cos.

Locke and Sydenham were not actual founders of modern systematic psychology and medicine, as were Aristotle and Hippocrates. They were, to a certain

[1] An address delivered on the occasion of the unveiling of a statue of Sydenham in the Museum of the University of Oxford, August 16, 1894.

extent, destructive critics of mistaken dogmas. They brought the exponents and students of mental and medical science back to observation and its conclusions, and removed them from speculations without data, and from misinterpreted authority. The merit of both lay in this, they rejected abstract assumptions and definitions not based on observed fact, and thus Locke made perhaps the greatest change in mental philosophy since the days of Plato, and Sydenham the greatest in medicine since the days of Hippocrates.

Locke and Sydenham were both students and practitioners in medicine at Oxford about the same time; each entertained for the other the highest respect and admiration. They studied man from different points of view, and each with a deep sense that they should so direct their experiments and observations that "Science . . . may grow day by day more clear and more efficient." "In this way the human race," said Sydenham, "may reap the advantages thereof generally and with safety, even after they themselves have been laid in their graves."

It would be impossible on this occasion to describe in full the condition in which Sydenham left practical medicine at his death, in 1689, or to discuss the merits of his own procedure in detail. Like those great men whose contemporary he was, Boyle, Newton, Locke, he was observer and interpreter of Nature, observer of fact under every condition of being and of change, interpreter so far as the knowledge and means of his age made interpretation possible. Confident in the rightness of his method, he dedicates in a careful paper his observations on the history and cure of acute disease to Robert Boyle, and receives himself a Latin poem on the occasion from Locke. He thanks Boyle, for "in the fulness of your humanity you have gone so far as to accompany me in visiting the sick." This method of observation and experiment, searching, scientific, according to the progressive means, methods, and gifts of the age, is now accepted as the basis, the only basis of therapeutics.

It remains to be added that Sydenham looked on his profession, dealing with the sufferings of mankind, as a solemn trust from God. This temper appears and reappears. "Since it is the will of God," he writes, "the Supreme Arbiter and Regulator of all things, that the human frame be, by nature, adapted to the reception of impressions from without, it follows that it must be liable to a variety of maladies." In the preface to his great work on acute diseases, he says: "Whoever takes up medicine should seriously consider the following points: First, that he must one day render to the Supreme Judge an account of the lives of those sick men who have been intrusted to his care. Secondly, that such skill and science as, by the blessing of Almighty God, he has attained, are to be specially directed toward the honor of his Maker and the welfare of his fellow-creatures, since it is a base thing for the great gifts of heaven to become the servants of avarice or ambition. Thirdly, he must remember that it is no mean and ignoble animal that he deals with. We may ascertain the worth of the human race, since for its sake God's only-begotten Son became man, and thereby ennobled the nature that He took upon Him. Lastly, he must remember that he himself hath no exemption from the common lot, but that he is bound by the same laws of mortality, and liable to the same ailments and afflictions with his fellows. For these and the like reasons let him strive to render aid to the distressed with greater care, with the kindlier spirit, and with the stronger fellow-feeling. In all cases it behooves each and all of those physicians who have the desire not only to *seem* but to *be* prudent and honest, to acknowledge and entreat the Divine goodness that from this they may look for wisdom and good fortune; and they ought not to be satisfied with simply giving health to the sick, but they should strive to add greater certainty to the art that they administer; and they should so direct their experiments that the science of medicine may grow day by day more clear and more efficient. In this way the human race may reap the advantages thereof generally and with safety, even after they themselves had been laid in their graves."

After these pregnant words I may be allowed briefly to notice the broad lessons we may learn even in our day of unprecedented research and knowledge—from Aristotle, Hunter, and Harvey, from Hippocrates and Sydenham, concerning the aims, methods, duties, and character of modern medicine. The modern attitude and scope of combined medical science and practice have one thing in common with the times of Sydenham and of Hippocrates, viz., the personal life and character of the true physician. These are unaltered and unalterable while the human race remains. We have all seen men in this respect like Hippocrates and Sydenham in our own day. I will name three physicians of England, of Scotland, and of Ireland —Latham, Alison, and Stokes—they were physicians typical as educated, scientific, gifted, practical observers—lovers of men and lovers of God, they all possessed eminently the qualities which are found in various degrees of perfection or imperfection in every age and every country, in every city and in every village where a skilful and beloved physician is found.

Hear the words of Latham addressing the students of St. Bartholomew's Hospital, within our memory: "Diseases are not abstractions; they are modes of acting, different from the natural and healthy modes—modes of disorganizing, modes of suffering, and modes of dying; and there must be a living, moving, sentient body for all this. This body must be your study, and your continual care—your active, willing, earnest care. Nothing must make you shrink from it. In its weakness and infirmities, in the dishonors of its corruption, you must still value it—still stay by it—to mark its hunger and thirst, its sleeping and waking, its heat and its cold; to learn its complaints to register its groans. And is it possible to feel an interest in all this? Ay, indeed it is; a greater, far greater, interest than ever painter or sculptor took in the form and beauties of its health. Whence comes this interview? At first, perhaps, it seldom comes naturally; a mere sense of duty must engender it; and for a while a mere sense of duty must keep it alive. Presently, the quick, curious, restless spirit of science enlivens it; then it becomes an excitement, and then a pleasure, and then the deliberate choice of mind. When the interest of attending the sick has reached this point, there arises from it, or has already arisen, a ready discernment of diseases, and a

skill in the use of remedies. And the skill may exalt the interest, and the interest may improve the skill, until in process of time experience forms the consummate practitioner. But does the interest of attending the sick necessarily stop here? The question may seem strange. If it has led to the readiest discernment and the highest skill, and formed the consummate practitioner, why need it go further? But what if humanity shall warm it? Then this interest, this excitement, this intellectual pleasure, is exalted into a principle, and invested with a moral motive and passes into the heart. What if it be carried still further? What if religion should animate it? Why, then happy indeed is that man whose mind, whose moral nature, and whose spiritual being are all harmoniously engaged in the daily business of his life; with whom the same act has become his own happiness, a dispensation of mercy to his fellow-creatures, and a worship of God."

The conception of preventing disease existed in the mind of Hippocrates in the widest sense, leading him into social, ethnologic, political, philosophic inquiries as to the material and moral cause of mental and bodily weakness in individuals and in nations, comparing the intellectual and physical conditions of Greeks and Persians, and tracing the various causes of their difference. The prevention of disease has become, in the memory of many now living, a part of the most ordinary routine of medical inquiry and practice, and is studied throughout the whole world. The care of the public health involves now complex inquiries into vital statistics, questions of districts and areas, social problems, engineering, meteorology, and geology, and the real but not the fanciful requirements for family life, whether in country or town. It is remarkable how much of this was foreseen by both Hippocrates and Sydenham.

Processes and modes of minute investigations into conditions normal and abnormal throughout all living beings, grasped by only a few half a century ago, have become parts of the earliest studies of every one entering the profession of medicine. Now they lay the foundations for the observation of facts in every state of health and of non-health in all living beings and for all clinical and therapeutic conclusions. But the temper and yearning of Aristotle, Hunter, Harvey, Hippocrates, and Sydenham must animate all, and amid the various phases of physiologic and pathologic progress may they be ever found in your Lordship's ancient University.

Oxford has bred many such examples besides Sydenham, Willis, Locke, Boyle. May she give to the world many, many more! May she continue to develop all the means she possesses for this blessed work, leaving to the resources of larger populations, in the Metropolis, in Edinburgh, in Glasgow, in Manchester and Birmingham, and of the great foreign cities where the care of thorough clinical instruction for which Oxford has not and cannot at present have the means of providing.

We ought, however, to be able to show here to our scientific students, without distracting them from their scientific work, the nature and extent of modern medicine. They may study the general principles of construction and administration of hospitals, the care of the sick poor in their own homes, by means of the staff of our large provident dispensary and of our trained district-nurses. They may and do now examine our village and rural populations, our extensive drainage-works, with our sewage-farm, and the works for the water-supply of our city. The development of each of these has opened a field for instruction not even dreamt of a few years since. Considerable knowledge of all these can be easily obtained by intelligent youths during the period of their general and scientific education in Oxford. What an enlargement of their sympathies and breadth of view before they enter on the vast field of clinical observation in the great voluntary or State hospitals now open to students.

As to the advance of actual and applied knowledge through scientific physiology and pathology since Sydenham's day, and as to the prospects of the near future of medicine through all races and conditions of men, by means of the great congresses of public health gathered from all parts of the world, this is not the time, even if I were able, for me to speak. It cannot be doubted that the recent development of knowledge of the causes, nature, and prevention of disease through the study of living animals and by bacterial research may produce ere long as great a change in the prevention of many diseases as Jenner in the last century produced for one. Though this may be the most astonishing result of the medicine of the nineteenth century, in relation to all the races of mankind, it is not the only result which in the twentieth century may be made known to man.

I beg your Lordship to accept this statue for Oxford, and so to keep ever alive before the future students of medicine examples of Hippocrates, Harvey, and Hunter, of Aristotle and Sydenham, and the many true and noble natures to be found in the annals of every civilized nation of the world.

CLINICAL LECTURE.

CONGENITAL DISLOCATION OF THE HIP.[1]

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, UNIVERSITY OF BUFFALO.

HERE are two little girls, aged respectively eight and eleven, who both have apparently some spinal curvature. Even through the clothing the abnormal gait and the deformity of the spine are noticeable. In the case of the older child the deformity is symmetrical, whereas the younger one shows a one-sided deviation.

Let us examine the older child more carefully. The gait is a peculiar sidling one, as if the hips yielded somewhat at each step. The hips project backward, giving the buttocks a strange appearance. There is an abrupt lumbo-dorsal angle in the spine, and the abdomen is correspondingly protuberant. With all this deformity, which has been noticed since early infancy, the child complains of no pain and of but little fatigue in walking.

The case presents the typical picture of bilateral congenital dislocation of the hips. Let me show you that the spinal curvature is only apparent, in order to compensate for the false position of the femora on the pel-

[1] Delivered at Buffalo General Hospital.

vis. By placing the girl flat on her back the deformity disappears. I will take some measurements while an assistant steadies the pelvis. Nélaton's line is drawn from the tuberosity of the ischium, around the hip to the anterior superior spine of the ilium. Normally, the tip of the trochanter is just beneath this line, but here the trochanter is an inch and a half above it, as traced with the dermograph. There is about the same displacement on the other side. By flexing and rotating the thighs, and pushing up and down, the trochanter moves more freely than it should, indicating that the capsules are relaxed.

The younger child, a sister of the other, presents essentially the same condition, except that it is located on one side. The compensatory deformity of the spine here is not so much an anterior curvature as it is rotation. The gait is, therefore, like that of a person with one leg shorter than the other. On drawing Nélaton's line I need not mark the position of the trochanter, as the child is so thin. It is about an inch and three-quarters above the line. On the other side its position is normal. The capsule is even more relaxed than in her sister's case.

It is rather a remarkable coincidence that these two cases should occur in sisters. There is no family history of such trouble, and there are other children of the same parents who are not similarly affected.

The question of operation is a matter to be very carefully considered. I should rather operate on the child that has the trouble on one side, for there would be only half the shock, and she is younger and more amenable to treatment. But I am not in favor of operating, even in the latter case. A cork sole under the foot of the affected side would correct the gait somewhat, although it would not relieve the condition of the hip. The older sister, of course, could not be helped in any such way, and apparatus designed to hold the hips in better position is irksome and cumbersome, and I am not much inclined to advise any interference.

This next child I have brought before you to illustrate the result of operation for congenital dislocation of the hip. The child was placed absolutely in my hands, to be dealt with as seemed best to me. About three months ago I did the new operation devised by Prof. Hoffa, of Würzburg, and reported by him at the Congress of German Surgeons in 1890. It consists in cutting down upon the head of the bone, loosening it from all connections and adhesions, including the muscular insertions about the neck, and then in cutting still further, and making a new socket for the head of the femur at the point where it ought to be. The innominate bone is reamed out if necessary. The parts are then sewed about the head of the femur, and an apparatus is used to hold the femur in its proper position until a new socket shall have formed. The operation is simple in theory, but difficult in performance, and its success has not yet been fully demonstrated. Prof. Hoffa told me personally that he was getting very encouraging results. I represented to the parents of this child that such reports had been made to me, and told them that I was willing to carry out the operation if they were willing to abide with the result.

The child rallied well from the operation, and the wound healed without delay. Now, the head of the bone is in its proper position, but it can still be pushed up into its old position, so that the child is wearing a hip-joint splint, by which she is enabled to walk, the weight of the body being borne, not so much by the outer rod of the splint as by a distinct attachment, a perineal support. The apparatus, which is a modification of my own device, has been on for only two days, and I shall advise that the child be not allowed to walk for many months. The splint consists of a long brace, with a joint opposite the hip and one opposite the knee, which is at present locked, but which can be loosened later, so as to permit the leg to be bent; a broad support behind the thigh connected with the metallic rod; and a perineal crutch, which can be removed at any time. When the apparatus is in place the weight of the body is transmitted through the crutch and metallic cross-piece to a brace underneath the foot. Like any ordinary hip-joint apparatus, this is held in place by a pelvic girdle, and has an arrangement for lengthening the outer bar as the child grows. Below, it is held in place by adhesive strips applied to the leg. At the upper end of the long rod I have had a pad made opposite the great trochanter, and intended to hold it down to its proper position. This is not a feature of the ordinary hip-joint splint.

I have, of course, labored under the disadvantage of never having seen the operation done by its originator, having learned of it only through the reports of cases and my conversation with Dr. Hoffa. There is good motion in the hip, and the child can herself kick up her leg. In fact, there is a little too free motion, and this retentive apparatus has been put on to keep the limb quiet for a number of months. It will be at least a year and a half or two years before the value of the interference can be judged. I have certainly not made the child any worse, and the hip, though not available for active use at present, is in its normal location. [Eight months after the operation the child's condition was satisfactory.]

I have shown you these three cases for their clinical interest and their instructiveness in the matter of diagnosis. Aside from the question of treatment, the diagnosis being easy, the condition is one of peculiar interest to the surgeon on account of its etiology. The very fact that many different hypotheses have been offered by different writers at different times indicates that the explanation is shrouded in difficulty. I think, however, that it is correct to maintain that all cases are not due to the same cause or causes, and that at various times various anatomical conditions operate to bring about the clinical result so well illustrated here to-day. Let me briefly run over the principal hypotheses that have been advanced in explanation of the condition, and which I have tabulated in this schema upon the blackboard. This is essentially the classification of Krönlein, who has studied the matter most carefully:

1. Causes traumatic by
   - *a*. External violence, as by a fall during pregnancy or by violent uterine contraction.
   - *b*. Injury during birth, particularly in breech-presentations.
2. Causes spontaneous, due to
   - *a*. Laxity and deficiency of ligaments.
   - *b*. Fetal hydrarthrosis, or perhaps even fungous degeneration of the joint, with effusion or possibly caries.

3. Causes involving peculiar positions of the lower limbs *in utero*:

a. By strong flexion of the thighs, with weakness of the cotyloid ligaments.

b. By pressure of the abdominal walls, the amniotic fluid being deficient, so as to cause undue adduction of the thighs.

4. Muscular contraction, due to some central nervous lesion in the fetus.

5. Paralysis of the peri-trochanteric muscles.

6. Arrested development.

This last is the most common cause, and is based on what is known as Ammen's theory. It has of late years received confirmation from the researches of many others. It rests upon a solid scientific basis, and, so far as museum-specimens go, is certainly the most common cause of the condition. It has been the cause of all the cases the specimens from which I have had the opportunity of examining. The anatomic defect may consist in premature ossification of the Y cartilage at the bottom of the acetabulum, or, more often, in a retarded growth of this cartilage and failure on the part of the three segments forming the acetabulum to properly develop. Another manifestation of this same arrest of development may be seen in malformation of the rim of the acetabulum, which may be almost or even entirely lacking. As a matter of fact, any developmental failure will permit and favor displacement of the femur. This theory is also favored by the fact that congenital dislocation of the hip is often associated with other congenital malformations, sometimes of serious degree. I have not been able to discover such an association in any of the three cases shown you to-day, but the clinical history of many other cases illustrates this general tendency. It should be added that, while the malformation at the hip is usually confined to the acetabulum, there may also be cases in which the head and neck of the femur are imperfectly developed, and essentially the same result is brought about.

By all means the most common form of dislocation is upward and backward on the dorsum of the ilium. It is this form that gives the instantly recognized deformity and the characteristic gait observed in these cases. Congenital dislocation forward upon the pubes, and even downward into the obturator foramen, has been described, but is exceedingly rare. The *ligamentum teres* is usually lacking. When present it is commonly enlarged and thickened, and put on the stretch, as it necessarily must be in supporting the weight of the body. Ordinarily the capsule is entire, but by attrition and wear and tear, it may become atrophied, and at least the upper part may almost completely disappear. Sometimes it also is thickened, and it may be constricted at the middle into an hour-glass form. Occasionally there develops a new rim on the upper margin of the false acetabulum.

Standing as these patients must stand, the pelvis is in large measure suspended by whatever is left of the capsular ligament and the *ligamentum teres*. The trunk above is tilted, as the center of gravity of the pelvis and of the lower part of the trunk is thrown forward. There is a compensatory throwing back of the upper part of the body, in order to maintain the erect posture. This accounts for the peculiar curve of the spine so characteristic, as well as the rotation of the spine that marks cases of unilateral dislocation. It often happens that this enforced lordosis is mistaken for the primary condition, instead of being recognized as purely secondary and compensatory. Another tendency is toward abnormal development of the pubes, the anterior portions of the ilia being made to approach each other gradually, while the ischial tuberosities separate. Thus the entire pelvis becomes misshapen. Fortunately, the ilium seldom becomes too thin to justify the excavation of a new socket when operation is otherwise indicated.

Should you ever be in doubt as to diagnosis in a case of suspected congenital dislocation of the hip, it is a simple measure to place the patient on the back and manipulate the thigh, when it will be found that the trochanter can be put through an excursion upward and downward, and often forward and backward, to a degree never permitted in the normal condition.

So far as prognosis is concerned, these cases seldom become worse and seldom better when left alone. The gait, however, becomes more characteristic, and while walking appears very difficult, it really is not painful, scarcely even tedious to the patient, except that it is necessarily slow. There is a street-sweeper in this city, a middle-aged man, dwarfed in stature, who has this condition extremely well marked. He works as hard as any of his fellows, but he is so clumsy in his motions that I often wonder that he has not been run over and maimed or killed long before this.

As the gait becomes more conspicuous with advanced life the lordosis increases to a certain degree, beyond which it does not advance. This condition, not being an active disease of the spine, is painless, and in fact the suffering connected with congenital dislocation of the hip is almost purely mental.

Naturally the very important question arises as to what can be done for relief. It is fair to suppose that if the condition is recognized when the infant first begins to walk—or if possible earlier still—and the child be kept in bed, with slight traction on the limbs, there would develop in course of time substitutes for the natural acetabula which would fulfil their purpose more or less satisfactorily. Unfortunately, children thus deformed are seldom seen by the surgeon at an age when this simple treatment would be of avail. Unfortunately, too, it is hard to secure the intelligent coöperation of parents and to inculcate lessons of sufficient patience. Were you to ask me how long to keep such an infant in bed, I could not give you any definite rule; but I should say at least two, perhaps three years. You well know how few parents will consent to enforced confinement of an otherwise healthy child for such a length of time, partly from mistaken motives of kindness and partly from the disinclination to assume the care which would necessarily devolve upon themselves.

If the dislocation be unilateral and be taken in hand early it will be quite possible to carry out the same principle of long-continued extension by means of a hip-joint brace. As between some such simple measure as this and the radical method resorted to in the first case shown you, the choice is seldom presented. The radical operation has been performed thus far by but few surgeons. The general opinion of those who have tried it is rather favorable. The patients, however, must be carefully

selected. The puny, squalid child is not a suitable case for any serious operation; nor is the one whose parents cannot give it the proper care, or for which accommodation in some suitable institution cannot be secured. Again, these cases should be taken at the earliest possible moment, and until I have more reason to advise it than I have at present, I should scarcely recommend operation in children over three or four years of age.

In the case of the two sisters just before you I have told the mother essentially this: that I could give her practically no hope in the case of the older child with the double lesion, but that in the case of the younger child, I thought the condition would justify operation; that this would probably do no harm, even if no good were accomplished, and that the prospect was fair for perceptible improvement, providing she could afford the necessary time and attention. The poorer class of people, to whom she belongs, must necessarily consult expense in these matters. She lives at a distance, and I am not willing to take the responsibility of the operation unless she can leave the child here as long as may seem best. She must also see her way clear to provide the necessary apparatus at the conclusion of my operative treatment, and this will entail an expense of $40 or $50. It is a great pity that financial considerations have weight in deciding what to do in any surgical case, but as you have more than once seen in this clinic, they sometimes form a very important factor, even when professional services are given gratuitously.

I think I may conclude what I have to say to you this morning by advising you always to represent to parents or responsible friends of a patient, as I have done in this case, that such an operation as is under consideration here is an experiment—a scientific and perfectly justifiable experiment, but nevertheless an experiment. It is such an experiment as I should not hesitate to have tried on any member of my own family under proper circumstances, but I would be quite unwilling to undertake it upon this little patient or any other unless the guardians of the child were satisfied to regard it in that light.

CLINICAL MEMORANDA.

MYELOMA: REPORT OF A CASE.[1]

BY JAMES B HERRICK, M.D.,
ATTENDING PHYSICIAN TO THE COOK COUNTY HOSPITAL,
AND
LUDVIG HEKTOEN, M.D.,
PATHOLOGIST TO THE COOK COUNTY HOSPITAL, CHICAGO.

Occasionally the bone-marrow becomes the seat of primarily multiple lymphomatous tumors, which are usually associated with grave anemic conditions. These tumors are described quite fully by Klebs[2] in connection with lymphoma under the special designation of myeloma (*Myelom*). They are, in other words, medullary lymphomas, lymphomatous tumors occurring apparently as primarily multiple growths in the medulla of bones.

The term myeloma can hardly be said to have acquired this special significance in American medical literature, and the various dictionaries define it as a tumor of bone-marrow, or as synonymous with encephaloid. Dock employs the term myeloma freely in his classic article on "Chloroma and its Relation to Leukemia."[1] In describing an illustrative case we have concluded to use the term myeloma in the restricted sense just alluded to, because the word is not associated so closely with any other growth or condition as to result in confusion.

According to Klebs,[2] v. Rustizky[3] was the first to describe as a peculiar form of neoplasm the primarily multiple tumors of bone-marrow. That the primary multiplicity of these medullary tumors is characteristic of myeloma has been established by all subsequent observations,[4] none of which disclosed a tumor of sufficient size and development to merit the distinction of being regarded as the primary focus; it must also be borne in mind that the tumors occur essentially in the bone-marrow, while growths in other organs are only occasional.

Microscopically the tumors consist of unusually wide blood-spaces without any definite walls, located in diffuse areas of round, lymphoid cells, with large nuclei rich in chromatin, dispersed in a wide-meshed, finely fibrillated, delicate network of connective tissue.[5]

Myelomas cause a bulging of the bone in which they occur; often the growth breaks through the compact layer and infiltrates the periosteum and the para-periosteal and peri-periosteal tissues. In this respect they differ from leukemic lymphomas in bone-marrow; neither is the histologic structure identical.

Klebs has seen the rapid development of myeloma follow what he calls typical, pernicious flagellate anemias, and speaks of their anemic basis as quite well demonstrated.

On account of the many shortcomings in the observations of the case about to be recorded, we do not feel at liberty to analyze the various cases in the literature with a view to establishing somewhat more definitely the nature of these growths and their relation to lymphoma, pernicious anemia, and leukemia, but there are a few instances of those described that bear such a marked resemblance to ours, and at the same time indicate a distinct relation to blood-diseases, that brief references to them may perhaps be allowed.

Nothnagel[6] describes *in extenso*, under the title *lymphadenia ossium*, an interesting case, the main points of which may be detailed as follows:

A twenty-four-year-old man suffered for a year and a half from attacks of severe pain in the sternum, the abdomen, and the long bones. There were periods of fever of exquisitely intermittent character, often of a distinct tertian type; there was progressive emaciation; no malarial parasites were found in the blood, and after inoculations from the blood, culture-media remained sterile; there was swelling of the sternum and of the extremities. The blood-examination showed the hemo-

globin-estimation to be 30 per cent, and 1,824,000 red corpuscles to the c.mm., with poikilocytosis, the presence of nucleated red cells, some leukocytosis, the polynuclear leukocytes, with neutrophilic granulations, being especially increased; there were also many lymphocytes, a few eosinophiles, and a few large mononuclear leukocytes with homogeneous plasma. The hemoglobin fell to 24 per cent. before death. The post-mortem examination showed the pelvis, the spine, the scapulæ, the clavicles, the sternum, and the ribs, as well as all the long bones, and some of the bones in the hands and the feet, to contain microscopically characteristic lymphomatous masses, *i. e.*, myelomas.

Coates[1] describes, under the title "multiple sarcoma of bone," an instance of myeloma in a forty-three-year-old man, in whom a sternal swelling had existed for five years. The whole of the sternum was replaced by tissue composed of round, polygonal cells; the first and second ribs on the left side were involved, and all the other ribs down to the fifth were loosened; there were a number of spindle-shaped swellings elsewhere on the ribs, and the whole vertebral column, except the upper two and the lower two vertebræ, was affected to the extent that the bodies of the vertebræ were replaced by tumor-tissue; there were masses in the humerus and in the left femur also.

Grawitz,[2] in an article entitled "Maligne Osteomyelitis und sarcomatöse Erkrankungen des Knochensystems als Befunde bei Fällen von perniciöser Anämie," details a case of anemia following typhoid fever, in which round-celled sarcomatous tumors developed in the cranium, the vertebræ, the femora, the humeri, the bones of the legs, the right clavicle, the ribs, and the sternum; there were also tumors in the liver, the right adrenal, and a disseminated involvement of the peritoneum.

Kahler[3] describes, under the title "Zur Symptomatologie des multiplen Myeloms," the case of a physician, forty-six years old, who was under observation for eight years. Severe pain in the upper region of the chest marked the onset of the disease. Attacks of pain, at times osteoscopic, at times in the course of various superficial nerves, at times visceral, were frequent during the course of the malady. Flattened, elevated masses appeared on the surface of the bones, particularly the ribs; at the end of six years there was marked kyphosis in the upper dorsal region. The inguinal glands very slowly enlarged during the last year, and finally a spontaneous fracture of the upper dorsal vertebra occurred. The autopsy, which was unavoidably incomplete, revealed the fracture referred to, a large splenic tumor, great fragility of many of the ribs, with partial disappearance of their cortical substance; and upon microscopic examination extensive osteoporosis, dependent upon the multiple development of a tissue with the characteristics of round-cell sarcoma.

Kahler calls attention to the bone-pains and bone-swellings, the limitation of the affection to the bones of the trunk, the absence of marked flexibility of the bones, and the final appearance of the tumors and of the enlargement of the lymphatic glands, as features enabling the differential diagnosis to be made between myeloma and osteomalacia. He regards albumosuria, which was present in this case, as a frequent symptom of multiple myeloma. Huppert[1] has described the urine of this case under the title "Ein Fall von Albumosurie."

[1] Loc. cit. [2] Loc. cit. [3] Loc. cit.

The following is the clinical history of our case:

Mrs. A. C., a Bohemian, forty years of age, was admitted to Ward 8 of the Cook County Hospital, March 22, 1892. The family history was negative. Menstruation, which still continued, had begun at the age of sixteen and had been regular and painless, though scanty of late. Four healthy children had been born after normal pregnancies and short, easy labors. There had been no miscarriage. No history of syphilitic taint, hereditary or acquired, could be elicited. The woman had enjoyed good health up to thirteen months prior to entering the hospital, with the exception of an attack of rheumatism several years ago.

In December, 1890, and in January, 1891, the woman had suffered from pain in the lumbar region and over the lower vertebræ and the sacrum. In February, 1891, she noticeed a small nodule over the lower end of the sternum. This was not at all painful, and enlarged so slowly as not to excite her alarm. But soon other swellings appeared on the face and chest, and her strength began to fail. Some of the nodules she thought had disappeared after being visible for a time. In January, 1892, she began to cough.

On admission in March, 1892, the following points were noted: The patient was much emaciated and very pale. There was edema of both upper eyelids, with slight pitting on pressure over the tibiæ. Several nodules were seen over the anterior chest-wall, the largest about the size of a hickory-nut, fairly firm, painless, slightly tender on pressure, and located at the junction of the ribs with the costal cartilages and of the latter with the sternum. There was some diminution in resonance, with loss of intensity of the respiratory sounds, over the bases of the lungs, and large and small moist râles could be heard over all parts of the chest both on inspiration and expiration. The examination of the heart was negative, as was that of the abdomen, save that deep palpation in the lumbar region caused some pain. The mental condition was good; the pupils were equal, regular, reacting to light and in accommodation. No paralysis or disturbance of sensation in any part of the body could be found. The urine was examined on March 25th, and the report showed twenty-eight ounces for twenty-four hours, the color yellow, the specific gravity 1020; albumin was present, 33 per cent. by volume; there was an abundance of leukocytes, and granular hyaline casts. The temperature at the hour of admission was 100° F.; the pulse 132, the respirations 42

A few days after admission a nodule appeared on the forehead just above the base of the nose. This remained prominent for a few days, and then gradually disappeared. At this time the patient was taking mercury and increasing doses of potassium iodid.

During the fifteen weeks' stay in the hospital there was never an elevation of temperature above 101°. For days at a time the thermometer registered between 97° and 99°. Twice the record shows 101° and five times 100°. The pulse varied from 90 to 140, occasionally being intermittent. Respiration was always a little rapid and at times labored.

Omitting details of several records which relate especially to progressive emaciation and weakness of the patient and to the description of new nodules as they appeared, we quote from the record of June 29th, at which time the following notes were made:

The emaciation was extreme and the patient very weak. The thigh could be encircled with a single hand.

[1] Prager medicin. Wochenschrift, 1889, No. 4.

The mental condition was fairly good, and patient spoke hopefully of her eventual recovery. The cervical, inguinal, and axillary glands were moderately and painlessly enlarged. The heart-sounds showed no murmurs; the second sound was accentuated; and there was no evidence of cardiac enlargement. Over either chest below the angle of the scapula there was dulness, with loss of vocal fremitus, and distant bronchial breathing. Near the upper limit of the dulness, bronchial breathing was marked and the vesicular element was detectable. Coarse and fine moist râles were present as at the first examination. There was abundant muco-purulent expectoration. Anteriorly there was resonance, in places hyper-resonance. The dulness on the right side extended from the sixth rib in the mammillary line to a point one inch below the costal arch. The smooth edge of the liver was palpable at this point. Palpation of the ribs showed no bony defects, but some of the ribs, *e. g.*, the third rib on the right side, yielded so readily under pressure as to make one extremely cautious in examining, lest a fracture should be produced. The edema of the left upper eyelid, which had always been much more marked than that of the right, still persisted. The pupils were apparently normal.

The nodular enlargements were located as follows: Over the center of the forehead, where there had previously been a node, could be felt beneath the freely movable skin a roughening of the bone. Above this was a small nodule. Just above and behind the right external canthus was an elastic swelling, over which enlarged veins showed distinctly. Over the left malar prominence was a nodule, walnut-sized, not tender, and seemingly quite firmly attached to the bone. The right clavicle at its middle was enlarged, and here there could be detected a new point of motion and crepitus. There had been no traumatic cause for this fracture. At the junction of the ribs with the cartilages, and of these with the sternum, were nodular enlargements, firm, not sensitive to pressure, varying from a size just perceptible up to the size of a large walnut. Over the inferior angle of the left scapula was a nodule. The seventh cervical vertebra was unusually prominent, and in the mid-dorsal region the spinous process showed what seemed to be a nodule. Over the inner condyle of either humerus were nodes interfering somewhat with complete flexion of the arm. There was another on the posterior border of the lower half of the left humerus. No distinct crackling sound could be made out.

The blood-count showed the relation between the colorless and the red corpuscles about normal, 1 to 350. There were 2,800,000 red corpuscles to the cubic millimeter, the percentage of hemoglobin, estimated by Fleischl's hemometer, being 45. Unfortunately, no stained specimens were made.

During the night of July 1st the patient was delirious. She died, apparently from exhaustion, at 5 P.M., July 3d. During the course of her illness she urinated quite frequently, and there was a slight tendency to diarrhea. The latter may have been due, in a measure at least, to drugs.

The clinical diagnosis was: Multiple sarcoma, involving the bones of the upper portion of the body; hydrothorax; probable intra-thoracic tumors; chronic bronchitis; chronic nephritis.

It is but justice to Dr. Christian Fenger to add that he made an ante-mortem diagnosis of myeloma.

The anatomic diagnosis was: Multiple tumors in the sternum, the ribs, the spine, the right clavicle, the left humerus, the right humerus, the left malar bone, the skull; invasion of the adjacent soft tissues and of the dura; tumors in the ovaries; fibrous perisplenitis; chronic nephritis, hydrothorax, and chronic bronchitis.

Inspection.—There was marked emaciation and whiteness. On the left cheek, on the forehead near the margin of the hair, on the inner surface of the left elbow, on the central part of the right clavicle, upon the sternum, and along the costo-chondral junctions, as well as elsewhere upon the ribs, were found subcutaneous nodules and

Photograph showing location of tumors.

masses having the following characteristics in common: They were elastic, flattened or oval, not connected with the skin, but apparently attached to the underlying bones; the skin was movable and free from any signs of inflammation; the clavicle and some of the ribs were freely flexible at the site of the masses; the size was variable, from that of a hazel-nut to that of a hen's egg, and those over the breastbone, the clavicle, and the cheeks were the largest. The skull felt rough about, and especially above, the areas in the forehead.

Internal Examination.—On making the usual long anterior incision and reflecting the soft parts, many of the masses over the sternum were cut through. They were reddish-gray on the section-surface. The sternum and the cartilages were removed by means of sawing some distance beyond the costo-chondral junctions. The peritoneum was empty and smooth. The pleuræ contained much reddish fluid. The heart was normal in size; there were no endocardial changes; the myocardium was quite firm, but there were a number of yellow areas present which gave the endocardial lining of the ventricles a speckled appearance. Both lungs floated and crepitated; the lower lobes were rather heavy and contained considerable dark-red blood; on pressure mucopus oozed from the cut bronchi. The spleen was adherent to the diaphragm; it measured 13 by 8 by 2.5 cm.; the cut surface seemed normal. The kidneys measured 11 by 6 by 2.5 cm.; the capsules were somewhat adherent, and there were many cortical cysts; the cortex was 5 mm. in thickness, and its markings were rather indistinct, there being many streaks and areas of yellow. Both ovaries contained a few small tumor-areas of reddish color and firm consistence; these areas were irregular in shape and size. The liver measured 28 by 21 by 7 cm.; and it was firm. The central area of the lobules was dark-red in color, the periphery being yellow. The gall-bladder, the stomach, and the intestines did not present any changes. The brain also was normal and the dura will be described in connection with the bones of the skull.

The bones. Both the external and internal surfaces of the sternum were irregular and covered with tumor-masses, which extended into the adjacent tissues so deeply that in some places the tumor-tissue was cut through in removing the bone; the mediastinum was

not deeply involved, however, and there were no nodules that occurred independently of the sternum. The entire sternum was thickened, most so in the upper part, where it measured from 4 to 5 cm. in thickness. The sternum was also soft and flexible, and in many places the entire bone-tissue was replaced by soft, reddish-yellow masses, while in other places it seemed distended by similar masses growing from the medullary part, so that the compact tissue was shell-like and thin, and over these points there was parchment-crackling or craquement on rather slight pressure. On dividing the breastbone vertically with a saw, the entire interior was found filled with a soft, reddish-gray or yellow vascular tissue, that distended the bone into a shell, and this was again penetrated freely and apparently *ad libitum* by the new tissue, which had accumulated underneath the periosteum, as well as spread out into the peri-periosteal structures; the junction between the first and second pieces was bony, and there were also spiculæ of bone here and there in the neoplastic masses. The bony shell was thickest near the lower end, but the entire sternum was much expanded by the new growth in its interior.

The ribs contained a large number of similar tumors, which projected underneath the pleura as well as outward; the pleura had not been penetrated at any point, but externally the periosteum had been ruptured in many places, and the new tissue had spread out into the adjacent structures. The nodules upon the ribs varied much in size, were usually oblong or oval, peculiarly elastic on palpation, and of reddish-gray color. There were two points of selection, apparently, as regards location, namely, along the costo-chondral junction and at the spinal attachment of the ribs; in front this produced an appearance not unlike the so-called rosary of rickets. On the left side there was a rather diffuse, flat swelling, involving the third, fourth, and fifth ribs, near the sternum, and the soft tissues between them. In many places the ribs bent readily without crackling; in other places the bone had been distended into fusiform shells that broke easily. There were no nodules involving the costal cartilages that did not at the same time remain connected with the ribs or the sternum.

Along the costo-vertebral articulations was a diffuse growth of new tissue which in some places involved the bodies of the vertebræ; removal of two of the dorsal vertebræ showed that the bodies had been largely replaced by soft tissues which, while allowing the bodies to retain their normal shape, had grown out into the surrounding soft parts. The central third of the right clavicle was expanded into a large, fusiform mass, through the middle of which the bone was completely absorbed, so that the clavicle consequently bent readily; this mass measured 15 cm. in diameter.

Large nodular masses were also observed upon the inner surface of the left humerus near the elbow-joint and upon the outer aspect of the head of the right humerus, but these were not incised for cosmetic reasons, as the permission to examine the body was not without restrictions. For the same reasons the large mass over the left malar bone was not incised. The character of these masses, as far as it was possible to make it out, has been detailed under the general description of the external appearance. No masses were found upon the bones of the pelvis or of the lower extremities, but no internal examination of these bones was made.

The skull presented the following peculiar appearance: Underneath the scalp in the frontal and fronto-parietal regions were irregular fungoid masses creeping out of the bone; the masses were of all sizes up to that of a silver quarter, and they were all somewhat flattened. There were also rough areas in the bone that suggested absorption of the soft tissue that probably once occupied them. In the front part the calvarium was in many places porous, and it was sawed through very easily, the resistance to the saw not being nearly as marked as ordinarily. Along the usual saw-incision the calvarium was much increased in thickness—more so in some places than in others; this was due to a growth of soft, red tissue in the diploë, which forced the two tables apart and crept through the bony shell freely both externally and internally, so that, roughly speaking, the entire anterior half of the inner surface of the calvaria was occupied by an almost continuous layer of this new tissue; corresponding to this extent the external surface of the dura was rough and presented fungoid masses, usually flattened, that fit into the honeycombed depressions in the bone.

The longitudinal sinus was empty and smooth. The internal surface of the dura over the right hemisphere presented one mass 1 cm. in diameter, located at the junction with the falx, 4 cm. above the crista galli; there were no changes in the subjacent pia. The changes in the skull and the dura extended as far downward as the root of the orbits in front, and to a corresponding part laterally; posteriorly the limits were marked by a line drawn across the top of the head from one external auditory meatus to the other. The frontal sinuses and the orbits were not examined. There were no changes at the base of the skull except in the hypophysis, which unfortunately was lost.

Microscopic Examination.—Sections were made from most of the medullary tumors and from the growths in the ovaries. The structure is the same in all, and consists of round, lymphoid cells, with quite large nuclei arranged in a finely fibrillated, at times almost homogeneous, matrix; in places they are very closely packed together, in other places more loosely. There are many blood-spaces of irregular size and shape found in the tumors, usually without any definite walls, the blood-mass being in direct relation with the surrounding wall of lymphomatous cells.

NOTE.—Ignorant at the time of the relation that might exist between these tumors and changes in the blood, we failed to make as complete observations as could have been desired; nevertheless we have deemed the case of sufficient value to merit this report.

A CASE OF FATAL NAUSEA AND VOMITING OF PREGNANCY.

BY W. D. JONES, M.D.,
OF RISING CITY, NEB.

MRS. S., twenty-two years old, a blond, of generally good health, except for a naturally weak stomach, but of a neurotic temperament, married two years, called upon me about March 1, 1894, complaining of slight nausea and occasional vomiting. After seeing her a second time, and feeling positive that her symptoms were due to pregnancy, I told her of my opinion. The existence of this condition was resolutely denied.

The patient kept about for two months, when her stomach absolutely refused to retain other than the blandest form of nourishment, and that in the minutest quantity. This being insufficient to support the vital forces, rectal alimentation was tried, with discouraging results. Up to this time digital examination had been refused, but was finally permitted. The uterus was found low down in the pelvis and retroverted. These conditions were corrected without any appreciable effect. The cervix and the cervical portion of the vagina were painted with Churchill's compound tincture of iodin, and boro-glycerid tampons were used without encouraging results. All of the usual remedies having failed to give relief, and the condition becoming more alarming—

the woman being nervous and sleepless, with a pulse of 120, slight jaundice, retro-sternal pain almost constant and accompanied with vomiting of bloody mucus and coffee-ground material—evacuation of the uterus was proposed as a *dernier ressort*. Accordingly the cervix was dilated and the lower uterine segment packed with 10 per cent. iodoform-gauze, in the hope of stimulating uterine contractions. Having failed to produce the desired effect, the packing was removed at the end of thirty-six hours and replaced by two medium-sized bougies. At the end of twelve hours these were supplemented by a third, which accidentally ruptured the membranes. There being slight and gradually rising temperature and complete uterine inertia, the bougies were removed at the end of forty-eight hours, and immediate instrumental evacuation of the uterus was determined upon. With the skilful assistance of Dr. East, a fragmental delivery was rapidly accomplished under chloroform, with the loss of only a slight amount of blood. The uterus was irrigated with hydrogen dioxid. Churchill's tincture of iodin was applied to the endometrium and the cavity packed with iodoform-gauze. There was no appreciable shock following the operation, and a few hours afterward the patient expressed herself as feeling better.

The temperature subsided to normal three hours after the operation, but the pulse gradually increased to 130, and the patient died twelve hours after the operation.

An autopsy was not secured until forty-eight hours after death. The body had been embalmed and was in a perfect state of preservation. Emaciation was decided, with marked jaundice of the surface. The epigastric fat was about half an inch thick and very yellow. The liver and gall-bladder were normal; the kidneys were abnormally soft and flabby. Only a tactile examination of the kidneys was made, as an exploration of the stomach alone was granted. At the pyloric end of the greater curvature a distinct erosion of the mucous membrane was observed, laying bare the minute submucous bloodvessels.

This case, I think, corresponds with three reported by Dr. Edward P. Davis, of Philadelphia, in The Medical News for June 2, 1894, p. 597.

A CASE OF HYDROPHOBIA.

By C. M. BOWCOCK, M.D.,
of Springfield, Ill.

On June 5, 1894, I was telephoned to come immediately to see a child that had been bitten by a dog. I found a little girl, three years old, whose face had been quite badly lacerated by the dog's teeth. Within ten minutes from the time the accident occurred I had washed and thoroughly cauterized the wound with silver nitrate, and directed the mother to keep the parts thoroughly cleaned by means of a 1 : 3000 solution of mercuric chlorid. On the following day I found the little patient getting along nicely. Eighteen days after the accident I found the injury nicely healed and quite healthy-looking, the scars not being in the least inflamed. Three days later the child was brought to me complaining of itching and soreness in the scar, with headache and slight fever. The cicatrix was cyanotic and tumid, the glands under the jaw were a little enlarged and slightly sore, and the child was quite nervous. On the following day I was called, to find the girl suffering with well-developed hydrophobia. The mere sight of water would cause slight spasms, and even speaking of water would make her extremely nervous. There seemed to be an entire absence of appetite, the child refusing all food, liquid or solid. She continued to be very restless until death. The pulse ranged from about 120 to 140, and was small and hard. The temperature varied between 101° and 101.5°. The pupils were very much dilated at times, especially in the presence of strangers. All movements increased the general nervousness. There was slight redness of the fauces. The bowels were very much constipated. Intelligence was not impaired in the least. The voice was indistinct in tone, speaking seeming to require quite an effort, and increasing her nervousness.

On removing the patient from one room to another the sight of water in a bucket at least six feet away induced quite a violent convulsive paroxysm. During such an attack breathing seemed quite difficult. On applying the hands to the patient's legs or arms general trembling of the muscles could be detected. The little patient rapidly grew weaker, and in the last two hours of life lay in a comatose state, passing away quietly.

Considering the short duration of the child's sickness she was very much emaciated indeed. The case ran a typical though very rapid course, death taking place about eighteen hours after the first appearance of the symptoms.

The dog was a large, male, white bull-dog, weighing about eighty pounds. As far as I can learn he was a strange animal, and must have wandered from some distance. When first observed he attracted attention by his peculiar behavior and rapidity of movement. He was seen to attack and kill a small dog, and to bite a cow and rush on. He bit at several other dogs and objects on one of our main streets, and his strange actions attracted general attention. After biting the little girl, by whose screams a neighbor was attracted, the animal attacked the latter also, but was killed before he could do further damage.

THERAPEUTIC NOTE.

STRONTIUM LACTATE IN NEPHRITIS.

By LEWIS J. BATTLE, M.D.
of Washington, D.C.

The Medical News for April 21st, 1894, p. 425, contains an interesting lecture by Prof. J. M. Da Costa, on the treatment of nephritis. Three instructive cases are reported in which strontium lactate was used, and the opinion is expressed that this agent is an admirable diuretic, especially in cases of acute nephritis. On June 5, 1894, I was called to a man, fifty-six years old, an employé in one of the departments here, who had enjoyed good health until last April, when he contracted a severe "cold," which was followed by rheumatism in the lower extremities. His appetite was variable, and at times he suffered with intense nausea. He was markedly anemic. He complained of persistent dull pains in the lumbar regions. His temperature varied from normal to 101°. There was pronounced dropsy of the

face, abdomen and legs. The urine was scanty and high-colored, and rather of a smoky hue. It had a specific gravity of 1010 and contained 9 per cent. by bulk of albumin. There were present also, blood, hyaline and epithelial casts. The patient was directed to go to bed, and a diet of milk was prescribed. The bowels were kept open with concentrated solutions of magnesium sulphate, and infusion of digitalis was given as a diuretic. When I found that this treatment did not greatly benefit the patient, I tried strontium lactate in doses of thirty grains four times per day, as recommended by Prof. Da Costa. The man's appetite soon improved; his anemia diminished; his dropsical condition ameliorated, and the urine, greatly increased in quantity, presented no blood, less albumin and fewer casts. The drug is deserving of careful and extended trial in cases of nephritis, acute, subacute and chronic.

NEW DEVICE.

A NOTE UPON THE VALUE OF DIRECT MASSAGE OF THE CORNEA AS AN AGENT IN THE TREATMENT OF CORNEAL OPACITIES.

Presentation of a New Instrument.[1]

By H. McI. MORTON, M.S., M.D.,
OPHTHALMOLOGIST TO ST. BARNABAS' HOSPITAL,
MINNEAPOLIS, MINN.

The large number of remedies that have been proposed to clear the cornea of scars or superficial infiltrations are but discouraging proofs that we have not as yet any one method of treatment that is eminently satisfactory. It may be observed, from their widely different local action, that the pathology of these formations has not been carefully kept in view by the advocates of many of the remedies proposed.

There is no great consecutive number of cases in which vision is impaired by an opacity that will yield to the same treatment, so far as a drug is concerned. The different conditions present demand different means of therapeusis: in the one case, a slightly irritating remedy; in the other, a decided irritant. It is not that I would advocate any new drug, but a method that facilitates the action of medicines in many cases, and even more, will in itself, I believe, do much toward the diffusion or entire dispersion of the obstruction to vision. The cure of peripheral opacities is usually demanded for cosmetic reasons alone, but in the case of a scar in the pupillary area, it becomes more than the disfigurement it causes, as it may greatly interfere with vision.

After any corneal ulceration a certain amount of the cellular infiltration present clears up, and in cases in which there has been little more than a loss of epithelium, an almost imperceptible scar remains. This is particularly true in the case of children. In such cases, very little of the true corneal tissue has been involved, the epithelium suffering most. There is a class of cases, however, in which the ulcer has left more or less decided loss of the cornea, which is partially or completely filled up with cicatricial tissue. In many cases treatment gives but unsatisfactory results. In a few of such patients I have, by a process of massage which I shall describe, been enabled to aid materially in rendering the cicatrix less dense. Of this, I am sure, and the diminished density will, of course, permit of much less diffusion of light and an improvement of vision that has been noticeable in some of the cases. The manner in which I have practised direct massage of the cornea during the past year and a half has been as follows:

The cornea is rendered insensitive by a 10 per cent. solution of cocain, which, at the same time, by its action upon the corneal epithelium, facilitates the entrance of the drug used. The head of the patient resting upon the knee of the surgeon, the eyelids are separated with the thumb and forefinger of the left hand, and the massage-spoon is held in the right. The cornea is gently rubbed alternately in a circular and radiating manner from one to three minutes, and this is repeated as often as is indicated in the individual case. It is to be remembered that the uvea, or region just external to the corneal limbus, nourishes the cornea, the lens, and the vitreous, and is the great lymph-producer for the eye, particularly the anterior segment. For this reason, I desire to lay stress upon the fact that these movements should not be confined to the area immediately adjacent to the opacity, but should be applied, not only all over the cornea, but also in the ciliary zone upon the sclera.

After the massage has been practised, I knead the globe with the thumbs of my two hands, carefully but thoroughly. By following out this plan the lymph-channels are thoroughly opened, and the activity of the lymph-currents increased. This in itself is not only a means of dissipating the opacity, but allows the medicament used an excellent chance for action. In massage through the lids, as spoken of by various authors, it is impossible to obtain the effect in a satisfactory manner, and for two principal reasons: in the first place, the manner of applying massage through the lids to the cornea, or any portion of the anterior ocular segment, is, if I may use the expression, a "blind" one. It is impossible for the operator to tell at just what point he is applying the massage. Again, the method is indirect, and cannot be as efficacious as when the massage-spoon

is employed. This instrument I devised about one year and a half ago, and I have used it continuously in suitable cases since. It is so arranged that the cornea is thrown into very small furrows, and it also will be noticed that any ointment used is held nicely between the forks, and can thus be "worked into" the cornea during the massage. I should like to add that this form of treatment has been of value in the deep forms of scleritis when used with the ointment of yellow mercurous oxid, and I have used it in the infiltration constituting interstitial keratitis, but am not yet ready to speak with any authority as to the result.

In pannus this procedure has been partially efficient, and in one case vision was recovered to a remarkable

[1] Read before the Minnesota State Medical Society, June 20, 1894.

degree. It must be borne in mind that this treatment is, as I have said, an adjuvant, and I do not pretend that it has any marvellous power. That it is rational in its action must be obvious; that it has yielded satisfactory aid in the treatment of corneal opacities in my practice I am sure.

In opacities following non-inflammatory conditions of the cornea it is of little avail, for here we have to deal with very different conditions. I am confident that it is far superior to massage through the lids; and the protection rendered the lens by the aqueous humor, and the necessary skill of the operator, make the danger of injury to the lens very slight indeed.

The instrument is made by Mr. E. B. Meyrowitz, of New York. A citation of cases, I believe, would avail little. I give my experience in the use of what I call direct corneal massage, and hope that it be extensively tried and found to be as valuable an adjunct to the therapeutics of corneal neoplasms as I have found it.

Dayton Building.

MEDICAL PROGRESS.

Successful Gastrorrhaphy for Perforated Gastric Ulcer.—Gilford (*Lancet*, No. 3692, p. 1369) has reported the case of a woman, twenty-nine years old, who presented symptoms of gastric ulcer at the age of twenty-one, when she vomited blood on two occasions. In the interval, though subject to dyspepsia of indefinite nature, there had not, until recently, been marked pain or return of vomiting. This last appeared to bear no relation to the ingestion of food, and the vomited matters were free from blood. Pressure over the greater part of the abdomen occasioned no pain, but at one spot that could be covered with a silver quarter-dollar the pressure of the finger caused acute pain. Appropriate treatment was prescribed, and for a time the woman improved, but in the course of four months pain and vomiting returned. Some two months later, after a breakfast of cold mutton and bread and butter, and while engaged in household duties, the woman was seized with agonizing pain a little above and to the left of the umbilicus. The pain extended to the middle and lower part of the sternum, and especially to the shoulder of each side. Respiration was mainly thoracic, and was restricted by the pain induced by deep breathing. The abdominal muscles were rigid and sensitive to pressure. There was nausea, but at first no retching or vomiting. The temperature was 96.8°, the pulse 68, regular and of normal size and tension. A diagnosis of perforation of a gastric ulcer was made and a solution of opium injected subcutaneously. Celiotomy was decided upon, and an incision three and a half inches long was made in the middle line. On opening the peritoneal cavity a small perforation with friable margins was found on the anterior wall of the stomach, near the center. The interior of the stomach was explored for other ulcers, but none was found, and the margins of the perforation were then excised. Ten silkworm-gut sutures were next introduced through the whole thickness of the stomach, including the mucous membrane. After the wound had been closed a tube was passed into the stomach and water poured into it through a funnel, to test the efficiency of the sutures. The approximation having been found competent, the abdominal cavity was well irrigated with boiled water and the wound closed, a bulbous, glass drainage-tube being first passed through, so that its bulbous extremity rested on the closed ulcer. For seven days the woman was fed with peptonized-milk enemata, varied occasionally with beef-tea and raw meat, six ounces being given from every four to six hours. On the ninth day the wound suppurated, the temperature rose slightly, and the woman appeared haggard and depressed. On the tenth day two tablespoonfuls of peptonized milk and one of beef-jelly were given every hour by the stomach. Three days later the diet was enlarged to include oysters and farinacea. On the fourteenth day the woman passed a stool that was said to have been capped with pus. On the seventeenth day the temperature rose to 103° and the pulse to 132, and the expression became anxious, sunken, and haggard. An exploratory examination was under consideration, when during the night the woman was suddenly aroused from sleep by an acute pain a little above and to the left of the umbilicus, and almost immediately afterward called out for the bed-pan. A pale, loose, highly offensive stool was passed, evidently composed principally of pus, and three other motions of a similar character were passed subsequently during the day. The temperature rapidly fell and did not again rise. The woman now speedily improved, and three weeks after the operation was sitting up in a chair. In the following year she gained in weight, and remained free from dyspeptic symptoms.

Trifid Uterus.—Depage (*Archives de Tocologie et de Gynécologie*, vol. xxi, No. 7, p. 550) has reported the case of a girl, twenty-two years old, in whom menstruation first appeared at the age of eighteen years, and who from this time had suffered with vague pains in the back and abdomen, becoming progressively more localized. The pain occurred in paroxysms setting in on the fifth day of menstruation, and lasting at times for ten days. Menstruation was otherwise normal. There was, however, a slight leukorrhea. Tumefaction of the abdomen had never been observed. On palpation a tumor about as large as a fetal head was detected in the left iliac fossa, extending a little to the right of the median line. The mass was slightly movable, appeared to fluctuate, and presented an irregular though not lobulated surface, and dipped into the pelvis. To the right and below, directly behind the pubis, a second tumor, harder than the first, and not fluctuating, could be felt; it was about as large as a fist and also dipped into the pelvis. On vaginal examination the cervix uteri could not be felt, but a tumor projected into the vagina. With the aid of a speculum the cervix was found displaced forward and to the right. It was almost effaced, and manifested itself as a small, round opening. By means of a sound the uterus was found to be displaced to the right; the bladder was likewise displaced to the right and was situated directly in front of the uterus. On conjoined vaginal examination and abdominal palpation, it was found that the two tumors were movable upon one another. It was at first thought that the condition was one of ovarian cyst, but it was finally concluded that there existed multiple subperitoneal fibromata of the uterus. Celiotomy was decided upon, and after opening the abdomen a fluctuating cystic tumor was found

in the left broad ligament, intimately connected with a solid tumor behind the pubis and projecting into the vagina. The cyst was adherent to both omentum and intestines. On introducing the hand into the right iliac fossa the ovary was found enlarged and cystic, and it was extirpated. It was found impossible to remove the cyst and the tumor through the abdominal wound, and after a ligature was applied to the pedicle of the tumor the abdomen was closed, a provisional dressing applied, and the woman placed in a position for the removal of the new formations through the vagina. An incision was made around the cervix, the uterus dissected from the bladder, the cul-de-sacs opened, clamps applied, and the tumor-mass removed. The wounds were closed and suitable dressings were applied. The patient made an uneventful recovery. The cystic tumor was found to involve the left ovary. The remainder of the mass consisted of a uterus with three divisions. One of these communicated with the right tube and one with the left tube. The third was a closed sac connected with the common neck of the other two. The walls of all consisted of typical muscular tissue and were lined by characteristic membrane and contained utricular glands. The explanation of the occurrence of the trifid uterus is thought to reside in the formation of a diverticulum from one portion of a bifid uterus, resulting from a failure of union of the ducts of Müller.

The Preservation of Organized Urinary Sediments, Particularly Tube casts.—BOHLAND (*Centralblatt für innere Medicin*, 1894, No. 20, p. 449) details a method for the preservation of organized urinary sediments. The morphotic elements are collected by sedimentation or centrifugation, the excess of fluid removed, the sediment washed with a physiologic salt-solution and then treated with Müller's fluid. The last is renewed three or four times during a period of two weeks. After removal of the Müller's fluid the sediment is hardened by means of absolute alcohol, which is renewed until it takes up no more color. The sediment can be thus kept, or if the supernatant alcohol is permitted to evaporate the sediment may be preserved in the dry state. Sediments thus prepared may be used for purposes of demonstration or instruction, or they may be additionally stained.

With the same end in view, SMITH (*Southern Medical Review*, vol. i, No. 1, p. 4) separates the sediment by permitting the urine to stand in a conical glass, or by the use of the centrifuge, the supernatant fluid being cautiously removed. To this sediment is added sufficient of a solution of 10 or 15 grains of chloral to the ounce of water to restore the fluid to its original volume. After the lapse of twelve hours the supernatant chloral is poured off and a similar amount of fresh solution added. This procedure is repeated twice or thrice, the final amount of fluid, however, not being more than half or third of the original. If the chloral-solution be renewed every three or four months, such a preparation may remain in good condition for a number of years. Microscopic preparations made with comparatively fresh solutions of chloral, mounted on perfectly clean slides, overlaid with clean covers, and well sealed, will remain in good condition for months.

Pulsating Empyema.—At a recent meeting of the Société Médicale des Hôpitaux, BÉCLÈRE (*L'Union Médicale*, 1894, No. 60, p. 718) presented a man, thirty-one years old, who, nearly three years before, had been seized with cough, and three months later with pain in the left side of the chest, together with other evidences of pneumothorax and effusion into the left pleural cavity, the apex-beat being situated at the level of the right nipple. Under suitable treatment the condition of the patient improved, and he was able to resume his occupation. A month before coming under observation the dyspnea suddenly increased without appreciable cause. The apex-beat was found in the sixth interspace on the right side, several inches from the median line. The left pleural cavity was occupied by an effusion, and the left side of the chest, corresponding to the sixth, seventh and eighth interspaces between the axillary lines, was moved in pulsation synchronously with the action of the heart. For the relief of the dyspnea thoracentesis was practised, and nearly six pints of pus evacuated, in which examination failed to disclose the presence of microörganisms. There was dulness on percussion over the entire left half of the chest; neither metallic tinkling nor a succussion-sound could be elicited, although on auscultation below the clavicle, at the same time as percussion was practised over any part of the lower third of the chest, a metallic sound could be heard. In the discusion RENDU expressed doubts as to the case being one of true pulsating empyema, as in this condition the effusion is usually circumscribed. He rather thought that the pulsation resulted from the transmission of the movements of the heart displaced and compressed by the large effusion.

Two Cases of Xeroderma Pigmentosum in One Family.—DE AMICIS (*Berliner klinische Wochenschrift*, 1894, No. 20, p. 467) has reported the occurrence of xeroderma pigmentosum in two brothers, six and four years old, respectively, without hereditary predisposition. When the elder was eight months and when the younger was one year old there appeared upon the face, the neck, the dorsum of the hands, and lower third of the forearms numerous spots, some reddish and telangiectatic, some lenticular and pigmented, others larger, blackish-yellow and deep-black in color. At the same time there occurred cicatricial and atrophic areas and infiltration of the margin of the lids of the eyes and ectropium. The skin was dry, rough, scaly, and parchment-like. When the elder child was five years old there appeared upon the face, and particularly upon the cheeks, an eruption of fungus-like elevations, varying in size from a pea to an almond; the same conditions appeared in the younger child at the age of three years. In the elder the nose became sharp and the alæ atrophic. Both presented notable enlargement of the epiphyses of the bones of the hand; one of the children presented numerous acne-pustules upon the face. Despite the most careful treatment the condition of the children failed to improve. Some of the new-formations disappeared spontaneously, leaving cicatrices; others were removed with a sharp spoon. Examination of the blood and of bits of removed tissue failed to disclose the presence of microörganisms. The tissue presented a granular, vascular appearance, with epithelial cells arranged as in lobular or tubular epitheliomata, and numerous cells undergoing degeneration.

SATURDAY, SEPTEMBER 1, 1894.

THE CRANIAL CHARACTERISTICS OF CONVICTS.

IN the search for a criminal type anthropologists have described certain characteristics of the human skull which they believe are more commonly found in convicts than in the population at large, and to which they ascribe a definite importance, considering them signs of inferiority or degeneration, and holding that the individuals presenting such marks must belong to an atavistic or degenerate variety of the race.

Crimes or acts of an anti-social nature are more common in the primitive races than in the more enlightened—at least it is claimed that they are more natural to the inferior races, and, therefore, criminals must be more akin to savages, and must, like them, more often present the signs of inferiority. Comparisons have thus been made between the skulls of convicts and those of savage races, of the insane and of the so-called *honest* individuals of enlightened nations, and the anomalies noted with an exactness that might well be followed in other fields of science. Thus it has been observed that the average capacity of the skulls of convicts (about 1455 c.c.) is below that of the skull of normal man (1500 c.c.). The term normal is here used to denote the population outside of prisons, who are apparently sound in body and in morals. LOMBROSO, the founder of the school of criminal anthropology, makes a further differentiation by claiming that the thief more often presents a very small skull-capacity than a normal one, while the murderer more often presents a very large capacity. A cranial capacity of from 1100 to 1200 c.c. is common among thieves, while a capacity of from 1600 to 1700 c.c. is more frequent among murderers. BORDIER has found that prehistoric man had a large skull-capacity.

No material difference has been found in the measurements of the horizontal circumference of the skull in different classes of society. A small circumference is as frequent among the normal as among convicts. As regards the cranial index, the race-factor plays so important a rôle that no generalizations are here possible. While LOMBROSO considers a brachycephalic skull common in Italian murderers, BENEDIKT finds dolichocephaly to prevail among German murderers, mesaticephaly in the French, and brachycephaly in the Russian.

As LOMBROSO shows, not only must the nationality be taken into account in a consideration of the cranial features, but even the smaller provinces show differences in the population. Thus, Piedmont, a province of Italy, contains a greater number of brachycephalics, while the inhabitants of Sardinia and Sicily and other provinces of Italy are mostly dolichocephalic.

Asymmetry of the skull has been considered an important anomaly. BENEDIKT finds that 50 per cent. of thieves examined present cranial asymmetry; BAER finds this in 12 per cent. of all criminals; while LOMBROSO's figures are 23 per cent. for criminals, 7 per cent. for the insane, and 4 per cent. for the normal individual.

This condition, however, is quite frequent among normal individuals. An investigation of the Königsburg collection of skulls, of presumably honest persons, showed that 25 per cent. were irregular in outline. LE BON, in making measurements of 300 skulls, could not find *one* perfectly symmetric. Even a greater asymmetry among convicts can be explained by the fact that many of these come from the poorer classes. In the first place, rickets and other diseases which result in premature union of the sutures or undue yielding of the bones are more common among badly nourished children than among the population generally. Secondly, accidents during pregnancy and labor are more likely to occur among this class than among those who are

well attended, and who are not required to engage in arduous labor during the period of gestation. Finally, the attention the child is likely to receive during its growth would be such as to influence the shape of its skull, as well as the rest of the body.

With some nations it has been the custom to artificially mould the heads of infants; but observers have never been able to discover any bad effects produced thereby. On the other hand, marked deformities have coexisted with perfect sanity and exalted character.

Another anomaly, supposed to be frequently present in criminal skulls, is the persistence of the frontal suture (sutura metopica). BORDIER claims to have observed this in 19 per cent., LOMBROSO in 12 per cent., but WELCHER has observed the same condition in 10 per cent. of normal skulls, and ANUTSCHIN, in an examination of 16,000 skulls, found the frontal suture persistent in 8 per cent. among Europeans; in 2 per cent. among American Indians; in 5 per cent. among Mongolians, and in 1 per cent. among Australians. From his observations he concludes that the higher the race the more frequent the presence of the frontal suture.

The inter-parietal bone, which results from a persistence of the suture between the upper and lower portions of the occipital bone at the superior curved line, and which has been named the Inca bone, because it is so commonly found in the skulls of Peruvians (60 per cent.), is observed in only 10 per cent. of normal Europeans, and in 10 per cent. of convicts, while it has been found in 30 per cent. of the insane. Sometimes an additional (pre-interparietal) bone is formed from the triangular Inca bone by a transverse suture.

A strongly developed crista frontalis along the inner surface of the frontal bone is often noted in criminal skulls. While it attains a height of 8 mm. in only 9 per cent. of normal individuals, it reaches this size in 20 per cent. of criminal skulls. This peculiarity is supposed to be due to premature union of the two halves of the frontal bone, and is common among the insane.

Wormian or sutural bones are frequently found in criminal skulls. SILVA observed them in 46 per cent. of criminals; LOMBROSO in 32 per cent.; SOMMER in 68 per cent. of insane, and in 28 per cent. of normal individuals; and RANKE in 20 per cent. of normal skulls. They are found in all of the sutures, but most commonly in the lambdoid.

A fossa is sometimes present on the inner surface of the occipital bone in the median line, and is called the fossa occipitalis mediana. LOMBROSO found it present in 16 per cent. of convict-skulls, and in only 4 per cent. among normal individuals. Among the lower races it occurs frequently, in the proportion of from 20 to 40 per cent. It is present normally in the lower primates, especially in the lemurs, but it is not found in the higher anthropoid apes. It serves for the lodgment of the middle cerebellar lobe, the hypertrophied vermis of the cerebellum. It has been found in 22 per cent. of the insane. BIELAKOW considers this middle fossa a certain sign of atavism. It is usually triangular in form, and varies greatly in size.

A retreating forehead is found in 36 per cent. of criminals, and in 18 per cent. of normal individuals, but RANKE has shown that this is an ethnic character. The Middle Germans are distinguished from the South Germans by a more distinctly retreating forehead, yet as a class the former are no more criminal than the latter.

A strongly-developed and projecting superciliary ridge was found in 58 per cent. of the 206 criminal skulls examined. This feature, combined with large orbits, is present in 25 per cent. of normal men, and in 29 per cent. of normal women, while it is found in only 19 per cent. of female criminals. The criminal woman shows the various anomalies less often than the criminal man, and many of these even less often than the normal woman.

The foregoing are the principal characteristics of the so-called criminal cranium. Other anomalies are met with, but less constantly than those mentioned. Most often several anomalies are found in the same skull.

It is only as they affect the structure or function of the brain that they can be considered as of any significance, but unfortunately all researches on the criminal brain have as yet failed to show where the centers for honesty, amicability, and chastity are localized. We are not yet able to discover a man's religious belief by physical diagnosis, and crime is often as much a matter of belief as is religion.

The criminal, the anti-socialist of one generation is worshipped as a god by the next. As HEGER well stated the case before the Congress of Alienists, held a few years ago at Antwerp: "The grade of intelligence and the social worth of men depend upon factors not to be determined by the cubic contents of the skull or the measurements of the brain." Ethically considered, we doubt if there is much

difference between the man who steals a ride on a freight car and the man who "corners" a real or fictitious market. Yet, socially the one is called a thief, and is committed to prison, while the other is termed a shrewd financier, and sent to the Senate to act as representative of an honorable constituency.

There can be no objection to the record of careful observation by criminal anthropologists, but when they undertake to compare the convict's skull with that of the man who is able to keep out of prison, because they consider the one criminal and the other honest, they are liable to commit the same absurdities as those who would discover a man of genius by his "bumps."

That criminal acts are often due to a diseased brain, no one can dispute; but crime is likewise caused by ignorance, by necessity, and very often by avarice; only the first cause, disease, is capable of demonstration. If degenerations are more common in the population of prisons than in the population at large, the fact simply means that degenerated criminals are the more likely to be unsuccessful and the less likely to escape conviction, and also the more likely to die in prison, and thus come to the notice of investigators.

In 1892, in the State of Pennsylvania, 15,669 persons were indicted for crime by the grand juries, and tried in court, and of these only 3669 were convicted and sent to prison. Who are the criminals?

OPHTHALMOLOGY AND THE EDINBURGH CONGRESS.

Nearly three years ago we called attention to the fact that so far as a large part of the practice of physicians in general is concerned a great medical discovery is widely ignored.[1] It is still alarmingly frequent, even in the United States, that the refractive and muscular anomalies of the eye as sources of general reflex trouble are overlooked, although ophthalmologists and neurologists have been persistently emphasizing the lesson for many years, and have been offering the most convincing proofs that in doing so they are neither hobby-riders nor wilful perverters of the truth. In many centers and by many physicians the recognition of the truth is a matter of routine practice, but even with us a vast deal remains to be done before the truth is in danger of exaggeration.

[1] Medical News, December 12, 1891, p. 691.

It is, however, most strange that in Europe, whence come at least the fundamental principles of ophthalmic science, in this birthplace of refraction, the actual application of these principles falls far behind that of the usage in our country. It would also appear that no amount of iteration and reiteration of the fact of this neglect is of much avail in bringing about any admission of it on the part of many of our European *confrères*. Errors of muscular balance that do not induce strabismus are not usually looked for, and unless an error of refraction is strikingly large it is often ignored. Personal inquiries recently made of opticians in several large English cities brought out the admission that a large, a very large proportion of all prescriptions for glasses are for non-astigmatic lenses and without anisometropic differences. In asking for the loan of a case of test-lenses of a large London optician it seemed a little strange to him that the cylindric lenses were wanted quite as much as the spherical.

An American oculist who fails to test for heterophoria every pair of eyes examined would soon find himself—where he is! But it is doubtful if the practice is very general abroad.

A noteworthy proof of these facts was presented at the medical congresses recently held in England. At the meeting of the British Medical Association at Bristol the authors of papers on refraction and reflex ocular neuroses were indeed permitted to read their communications, but not a word of discussion upon them was allowed. At the International Ophthalmological Congress held at Edinburgh papers of the same character were put off till the last hour of the session; the readers were, we were about to say, bullied into silence or an equally ridiculous condensation, and the President permitted himself to announce that as these papers contained nothing new all discussion must be omitted. Many members of the Congress will long carry with them a vivid remembrance of the last hour of the Congress, a remembrance curiously compounded of amusement, astonishment, and disgust.

It is not permissible to impute unworthy motives, but it is a fact worth mention that the contributors thus dismissed with what seemed flagrant discourtesy were Americans who had been invited to contribute, and who had come a far greater distance than other members. Much has been written concerning the geographic distribution of disease, but little has been written of the more interesting geography of medical prejudices and insularities.

It might with justice be asked, either generally of most medical gatherings, or specifically of the Edinburgh Congress, that if only the absolutely new were allowed expression, and useless prolixity were always tyrannically silenced, what would then be the size of the printed volumes of the *Transactions?*

If one visits a foreign eye-hospital it is not dreamed that anything but operations (and most operations, it goes without saying, are cataract-operations) are interesting or worth witnessing. Every conceivable shade of difference in operating for cataract is emphasized, even harped upon, until one is both very much amused and very much bored, and one asks himself if ophthalmology begins with this millimetric Niagara and ends with a stick of cupric sulphate. Likewise in congresses, as one humorous and human speaker at Edinburgh said, everyone comes loaded to the mouth with descriptions of his own peculiar method of operating upon cataract, and returns home fully convinced that that method is absolutely the best, and determined to make no change whatever in it. In these meetings the cataract-controversy rolls on without check or limit until some one whispers granular lids, and the fugue then takes a new movement and lease of life.

Despite all minor differences and dissensions, there is among a large number of excellent and conservative oculists a perfect unanimity of conviction, buttressed by incontrovertible clinical demonstrations:

1. That the eye is a frequent source of functional systemic disturbance, headache, and multiform nervous and nutritional abnormality.

2. That errors of refraction, often of slight degree, are the starting-points of these reflex neuroses, as also of localized ocular diseases.

3. That muscular imbalance also is a frequent cause of the same disturbances.

It would appear natural that, in view of the evident perfection of technique and the wearing out of interest in the old problems of ophthalmology, eye-specialists would welcome an extension of their science into new fields, where, moreover, trustworthy testimony declares there is much new truth to be learned on our part and much old disease to be relieved on the part of patients.

Discourtesy to individuals and even to nations may readily be pardoned, but discourtesy to medical progress is genuine sin against the scientific Spirit, and is not to be forgiven. Let us hope that when the next Ophthalmic Congress meets, six years from now, and in the country of Donders, it will be more considerate of a medical truth and of those who urge its value.

EDITORIAL COMMENTS.

Notes upon the Meeting of the British Association for the Advancement of Science.—The meeting of the B. A., as it is colloquially called, held at Oxford last month, was a most excellent one, as all who were present agree. The number attending was 2321; the receipts, $10,675. The gathering was a model of dignified and sincere interest in knowledge, of freedom from "politics," of large-hearted and kind-hearted hospitality, both personal and collective, and it was held in a "city of colleges," of learning, and of antiquarian and esthetic interest unsurpassed in the world. If one wearied of the strain and excitement of new scientific thought and discovery looking forward into dim futurity, a step brought him to walks and meadows knowing nothing of these things, or to cloisters and chapels looking backward to a dim antiquity.

Most happy was the presidential address of the Marquis of Salisbury on the unsolved riddles of science, or, as one might name it, the nescience of science. Three entities lie at the foundation of all existence and all knowledge: matter (atoms), life, and the ether. With all the discoveries of science, with all the progress of the human intellect, no hint or glimpse has been gained as to the origin of any of these. The mind cannot even think of any theory of their origin. It was a happy thought of this perfect type of man of the world, as well as, in many senses, master of the world, to tell the greatest gathering of scientists how things scientific look to that world. There are few things more ridiculous than the cock-sure "evolutionist" and "scientist" who, puffed up with his "little dangerous knowledge," thinks all mysteries have been solved, and that all things are "explained" by mechanics and the "struggle for existence." Perhaps even he may learn the need of some intellectual modesty from the official assurance that "we live in a small bright oasis of knowledge, surrounded on all sides by a vast unexplored region of impenetrable mystery." The chancellor of England's greatest institution of learning, the president of the world's greatest scientific body, quotes with hearty assent the following words of the world's greatest living physical scientist:

"The hypothesis of natural selection does not contain the true theory of evolution, if evolution there has been in biology. . . . I feel profoundly convinced that the argument of design has been greatly too much lost sight of in recent zoölogical speculations. Overpoweringly strong proofs of intelligent and benevolent design lie around us, and if ever perplexities, whether metaphysical or scientific, turn us away from them for a time, they come back upon us with irresistible force, showing to us through Nature the influence of a free will, and teaching us that all living things depend on one everlasting Creator and Ruler."

As teachers of physiology, hygiene, and therapeutics, the words also warn us of a truth and a duty too often forgotten or denied.

Before this our readers have doubtless learned of the announcement of the new element discovered by Lord Rayleigh and Professor Ramsey, and made public by them at the Oxford meeting. The secret had been well kept, but it was our good fortune to be present at the meeting of Section B when the communication was made, and to talk with the authors afterward concerning their great discovery. It is indeed most noteworthy that a new element should have existed in the air that chemists have been breathing and investigating since science began. The discovery will perhaps win the Smithsonian Institution prize of $10,000. The authors do not therefore give a name to the "gas," nor even do they publicly state that it is a new element they have discovered. Despite some adverse criticism and the evident need of confirmation by other researches, there can be but little doubt of the elemental nature of "crypton," as the "gas" will probably be named. It is present in mechanical mixture with the nitrogen of the air in the proportion of about 1 per cent., and has a density of a little less than 20. It is quite impossible to foresee what may be the practical uses of the discovery to hygiene and to medicine. Discoveries usually lead to uses different from what the discoverers dreamed of, as, for example, the history of tuberculin proves; and we may soon learn of most practical benefits to the world arising from some ingenious application of the knowledge of this small amount of apparently inert gas, which, hitherto unknown to physiologists, we have been breathing every minute of our lives.

Many good papers were read having a more or less important relation to medicine. We have space to allude to but a few.

DR. A. BERNSTEIN, of Berlin, read a paper on "The Chemical Action of a New Bacterium in Milk." This bacterium, which is very small, has the property of rapidly making sterilized milk transparent, the change beginning at the top and proceeding downward. No gases are evolved and no coagulation takes place. The casein and other proteids in the milk are converted into peptone. In order to apply this fact to the production of peptonized milk, useful as an article of food, a small quantity of milk in which the bacteria are growing is mixed with a considerable quantity of fresh milk from which the cream has been removed. The mixture is kept at a suitable temperature, and fresh quantities of milk are added from time to time. When the whole liquid has become transparent it is boiled in order to kill the bacteria and coagulate any casein that remains unaltered. The product is a reddish, slightly acid liquid, with an aromatic odor. By adding along with the bacterium some pure yeast that has the property of attacking milk-sugar an alcoholic preparation can readily be obtained. In all probability the same or a similar bacterium plays an essential part in the ripening of cheese.

MR. L. COBBETT, in a paper on "Local Immunity," described certain experiments in which he had found that tissues which had once been the seat of erysipelas retained the power of reacting more energetically than normal tissue when inoculated with the sterilized products of cultures of the erysipelas-organism. He suggested that immunity might be explained as being due to an ability on the part of the tissues to react to chemic substances produced by bacteria.

DR. LORRAIN SMITH and MR. TREVITHICK contributed a paper on "A Form of Experimentally Produced Immunity," in which they described the results of experiments undertaken by them in order to test the influence of various conditions in producing susceptibility to disease. In cases in which an irritating powder had been injected into the pleural cavity of animals such animals were subsequently found to be more refractory to certain diseases.

To the anti-vivisectionist movement Professor Schäfer in his presidential address credits the following results: 1. The establishment of the Physiological Society; 2, the passing of the Cruelty-to-Animals act, which stands as a guarantee that the excesses formerly charged to physiologists are not possible; 3, the establishment of the Association for the Advancement of Medicine by Research; 4, the re-establishment of the Section of Physiology of the British Association. These results Prof. Schäfer ascribes to the anti-vivisectionists on the principle that "the blood of the martyrs is the seed of the Church." It would almost seem to be the logic of the situation, therefore, that vivisectionists should join hands with the "antis" in order to stimulate scientific research. We doubt if scientific enthusiasm and research has had such an ignoble origin.

When treating of the attraction-particle, the thyroid gland, the supra-renal capsules, and the pancreas, Prof. Schäfer is more interesting and convincing:

"There is no organ of the body, however small, however seemingly unimportant, which we can presume to neglect; for it may be, as with the supra-renal capsules, the thyroid gland, and the pancreas, that the balance of assimilation and nutrition, upon the proper maintenance of which the health of the whole organism immediately depends, hinges upon the integrity of such obscure structures; and it is the maintenance of this balance which constitutes health; its disturbance, disease. Nor, on the other hand, dare we, as the investigation of the attraction-particle has shown, afford to disregard the most minute detail of structure of the body.

> 'All is concenter'd in a life intense,
> Where not a beam, nor air, nor leaf is lost,
> But hath a part of being.'"

Sweat-shops and Smallpox in Chicago. — We recently took occasion to point out the likelihood of transmission of infectious disease through the intermediation of so-called sweat-shops,[1] and the first special report by the Chief Factory Inspector of Illinois on the epidemic of smallpox that recently prevailed in Chicago brings confirmation of the views then expressed.

The factory-laws of the State of Illinois provide that in case articles manufactured in sweat-shops or factories within the State are found by the factory-inspector to be infested with vermin or contaminated by infectious or otherwise dangerous material, these articles shall be destroyed by the local health-officer upon the demand of the chief inspector.

It appears from the report that there are 950 licensed sweat-shops for the manufacture of clothing in Chicago, and about 25,000 other rooms in which garments are made. The principal factory-inspector, with ten assist-

[1] THE NEWS, June 23, 1894, p. 697.

ants, had enough to do previous to the epidemic in securing compliance with the provisions of the law regulating child-labor. In the fall of 1893 a few cases of smallpox appeared in Chicago. In January there was a real epidemic, confined almost exclusively to a radius of ten blocks surrounding the smallpox hospital. This institution is in the hands of a charitable organization, but is practically farmed out by the political machine, and is wholly beyond control of the Health-Commissioner, both from a medical and from a sanitary standpoint. This institution undertook to care for so many cases and the place became so overcrowded, and the death-rate became so appalling, that the knowledge of its condition caused the people to refuse to permit the removal of members of their families who happened to be stricken with the disease. Then the authorities tacked yellow cards, usually in an inconspicuous position, upon the buildings in which cases arose, and allowed the disease to spread for a month or two. Under these circumstances, the duty of the factory-inspector evidently called for the protection of consumers of ready-made clothing from the dangers of smallpox contagion carried by the clothing made in sweat-shops in which persons were suffering from this disease. The inspector therefore informed 176 Chicago tailors and wholesale dealers in clothing, that have their work done by sweaters, that smallpox was epidemic and that there was danger of infection, and also called attention to the provisions of the law for the destruction of infected goods. Only a few of the manufacturers paid any attention to the suggestion of the inspector, so that it became necessary to adopt other means to secure compliance with the spirit of the law. The first goods were destroyed on May 12th by a health-commissioner under a threat of mandamus.

There does not appear to have been that co-operation between the local health-officers and the State Board of Factory-Inspection that the exigencies of the case demanded. In the meantime smallpox spread in various parts of the Western United States. On this account the various State boards of health were aroused, and a conference was held in Chicago on May 10th. The result of this conference was, strangely enough, the contribution of a fund of several thousand dollars by the manufacturers of clothing that employed Chicago sweaters, to be expended in the inspection of sweat-shops and in vaccinating their workers, the disbursement and the work to be under the direction of the Illinois State Board of Health; on condition that the State of Illinois, through its State Board of Health, guarantee the non-infective condition of the clothing manufactured in the sweat-shops of Chicago. The report of the factory-inspector shows that this inspection was wholly ineffectual, so far as securing to the consumers of clothing immunity from the disease was concerned, and the report is the strongest argument that has lately been put forth for the total abolition of sweat-shops' work.

It should be the duty of every medical man in the country, as well as in the city, to demand the protection of his families from the danger of small-pox and other infectious diseases, by such legislation as will require all garments to be labelled to indicate the condition under which they are made; then it would be possible for purchasers to demand factory-made goods and to refuse their patronage to stores through which infection might come with sweat-shop-made clothing Local boards of health could thus interdict the sale of this dangerous commercial product.

The Insidious Reading-notice.—We regret to see the reading-notice (and of nostrums at that) creeping into the otherwise clean and interesting columns of our respected cotemporary *The Canadian Practitioner*. It is but recently that we had occasion to congratulate the *Practitioner* on the elimination of interleaved advertisements from among the pages of its text. We were encouraged to hope that its example would not be without influence upon other journals and that its action might be viewed as a promise of a finer discrimination in general in the acceptance of advertisements by medical journals.

SELECTION.

THE NOSE AS A SOCIAL TEST.

A very interesting investigation into the habits, customs, physical characteristics, and religion of the natives of Northern India, initiated by Mr. H. H. Risley, and carried on under his supervision by the Indian Government, may be mentioned on account of the illustration it affords of the value of exact anthropometric methods in distinguishing groups of men. In Mr. Risley's examination the nose, instead of being vaguely described as broad or narrow, is accurately measured, and the proportion of the greatest width to the length (from above downward), or the "nasal index," as it is termed (though it must not be confounded with the nasal index as defined by Broca upon the skull), gives a figure by which the main elements of the composition of this feature in any individual may be accurately described. The average or mean nasal indices of a large number of individuals of any race, tribe, or caste offer means of comparison which bring out most interesting results. By this character alone the Dravidian tribes of India are easily separated from the Aryan. "Even more striking is the close correspondence between the gradations of racial type indicated by the nasal index and certain of the social data ascertained by independent inquiry. If we take a series of castes in Bengal, Behar, or the North-western Provinces, and arrange them in the order of the average nasal index, so that the caste with the finest nose shall be at the top, and that with the coarsest at the bottom of the list, it will be found that this order substantially corresponds with the accepted order of social precedence. The casteless tribes who have not yet entered the Brahmanical system occupy the lowest place in both series. The fisher castes are a trifle higher in the scale; the pastoral, the cultivating, and a group of cognate castes—from whose hands a Brahman may take water—follow in due order; and from them we pass to the trading and the landholding classes, and the upper crust of Hindu society. Thus, it is scarcely a paradox to lay down as a law of the caste organization in Eastern India that a man's social status varies in inverse ratio to the width of his nose." The results already obtained by this method of observation have been so important and interesting that it is greatly to be hoped that the inquiry

may be extended throughout the remainder of our Indian Empire.—*The Presidential address of* Sir W. H. Flower, F.R.S., *on Anthropology, before the British Association for the Advancement of Science.*

REVIEWS.

The After-treatment of Cases of Abdominal Section. By Christopher Martin, M.B. (Edin.), F.R.C.S. (Eng.), Surgeon to the Birmingham and Midland Hospital for Women. 8vo, pp. 48. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited, 1894.

The author of this little work tells us in his preface that it embodies the experience gained in the management of over one thousand cases, mainly in association with Mr. Lawson Tait. Hence it will not surprise the reader to find that the views and methods presented bear more or less distinctly the impress of that bold and skilful surgeon. They are very decided and very forcibly put, and may be read with profit not only by beginners in abdominal surgery but by many who are more advanced.

On one or two points we take issue with Mr. Martin. In speaking of drainage he mentions a number of conditions requiring this measure, and among them "where, from any cause, free oozing of blood is taking place into the peritoneum," or, again, "where there is reason to believe the bowel or the bladder has been injured." We doubt the propriety of closing the abdominal wound while blood is escaping freely into the cavity; and we think that if the surgeon suspects damage to the bowel or the bladder he ought to investigate it, and if possible repair it. Of course, there are exceptional instances in which such risks must be run in the endeavor to avoid greater dangers which are imminent; but they are, fortunately, very rare.

Again, our author several times speaks with favor of the injection of "a weak solution of perchlorid of iron" into the peritonial cavity to check bleeding. How strong a solution he would use he does not state; but we cannot regard the practice as one to be commended.

As a whole, this book must be welcomed as a very valuable summary of the results of a large experience in abdominal surgery.

A Manual of Diseases of the Nervous System. By W. R. Gowers, M.D., F.R.C.P., F.R.S. Second edition, revised and enlarged. Vol. II. Diseases of the Brain and Cranial Nerves, General and Functional Diseases of the Nervous System. Philadelphia: P. Blakiston, Son & Co., 1893.

The first volume of this edition of Gowers' *Manual* has already been favorably reviewed in The Medical News, so that it will only be necessary to briefly call attention to the second volume, the revision of which, like that of the first, is not merely in name. The anatomy and physiology of the cranial nerves and of the pons and oblongata are particularly well presented; and the entire discussion of the structure and functions of the brain, including localization, is just of the character calculated to assist the student and general practitioner. Neurasthenia is not discussed from the American standpoint. Gowers believes "there is no more justification for regarding neurasthenia as a definite malady, as a disease due to a definite morbid process, or even as an affection characterized by a well-marked group of symptoms, than there is for adopting a similar course with regard to 'debility' among general diseases." While not fully in accord with this view, it is interesting and healthful to read his brief discussion of the subject of neurasthenia, at the same time having in mind the elaborate monographs of Beard and Cowles.

No matter what may be its excellences, some fault can always be found with a book. The numerous illustrations, although nearly all are well calculated to teach what the author intends, have not been well reproduced. In this, as in the first volume, a few affections, such as akromegaly, erythromelalgia, and angio-neurotic edema, which are now generally discussed in neurologic text-books and treatises, are omitted. This volume, as the preceding one, shows that the author is not merely a clinician, but also a practical pathologist, illustrations of his own pathologic work appearing in many places. Although by no means overlooked, bacterial pathology has not, perhaps, received full consideration. The present volume contains 1050 pages of printed matter, not including the index, and with the preceding volume makes a work of about 1700 pages. The clinical portion can scarcely be surpassed. The book continues to be what it has often been pronounced, the best text-book on nervous diseases in any language. As a practical work for students and practitioners it has held first place for nearly ten years, and will continue to do so for many years to come.

The Etiology of Osseous Deformities of the Head, Face, Jaws, and Teeth. By Eugene S. Talbot, M.D., D.D.S. Third Edition. 8vo, pp. 487. Chicago: W. T. Keener Company.

The fact that a book devoted entirely to the deformities of the head and teeth should have entered upon its third edition is an evidence that the dental profession has devoted a great deal of persistent labor to these subjects. While the work primarily thus appeals to a special class of practitioners, medical men cannot fail to be impressed with the fact that a thorough knowledge of the forms of the jaws, teeth, and related parts is essential to a proper conception of the causes of variations in the anatomy of the head.

The author rejects the opinion generally held that irregularities of the teeth and jaws are the results of local conditions. A number of original devices for measuring the hard palate are described, but the reflection cannot be avoided that this portion of the work would have been strengthened if the methods pursued by others, notably by Virchow, Turner, and Flower, had been noted. Want of uniformity in this and other matters in detail of craniometry make it almost impossible to apply the results obtained by one author to those of others. Usually we might have expected in a work of the character before us a judicial expression upon the entire matter of jaw-measurements. In like manner we would naturally look for some account of the contributions of such observers as Welcker and Aeby. The work is extensively illustrated.

A MANUAL OF INSTRUCTION IN THE PRINCIPLES OF PROMPT AID TO THE INJURED; Including a Chapter on Hygiene and the Drill Regulations for the Hospital Corps, U. S. A. By ALVAH H. DOTY, M.D., Major and Surgeon, Ninth Regiment N. G., S. N. Y., late Attending Surgeon to Bellevue Hospital Dispensary, N. Y. Second edition, revised and enlarged. 8vo, pp. xvi, 304. New York: D. Appleton & Co., 1894.

As this work is designed for the instruction of non-medical rather than medical persons, the author has very properly preceded the consideration of his subject by an elementary, but none the less useful, consideration of the bony skeleton, and a short sketch of the physiology of the different organs. The main object of the book is satisfactorily attained by that portion devoted strictly to "Prompt Aid to the Injured," and it can be studied with advantage by those officials of military and semi-military organizations whose duties render them liable to be the first to come to the aid of the injured.

In the section on poisons the use of the somewhat antiquated stomach-pump is advocated, although in the same paragraph the use of the stomach-tube as a substitute for the stomach-pump, when the latter cannot be obtained, is very well described; and it is certainly a much better method of emptying the stomach of its contents.

The author has included a section upon hygiene, and the usefulness of his work is greatly augmented by the addition of the drill-regulations for the Ambulance Corps of the U. S. Army.

AËRO-THERAPEUTICS, OR THE TREATMENT OF LUNG-DISEASES BY CLIMATE. Being the Lumleian Lectures for 1893, with an Address on the High Altitudes of Colorado. By CHARLES THEODORE WILLIAMS, M.A., M.D., Oxon, F.R.C.C. London: Macmillan & Co., 1894.

THE feeling of partial disappointment with which one finishes the perusal of this both timely and instructive volume is no doubt due to the too comprehensive nature of the title. The term "Aëro-therapeutics" implies much that is neither touched upon nor intimated in these lectures. On the other hand, atmospheric influences constitute but one of many factors discussed by our accomplished author. "The Climatic Treatment of Tuberculous Patients," while somewhat trite, would have been an accurate and therefore not at all misleading title for the work.

At the same time, we heartily thank Dr. Williams for thus aptly and freshly presenting a subject which is rapidly increasing both in interest and importance, and we may at some future day take occasion to discuss it more adequately than can be done within the limits of a brief and formal review. It may be added that the work is a valuable addition to our rather meager literature on the subject of climatic therapeutics.

NEWS ITEMS.

The Mississippi Valley Medical Association will hold its twentieth annual meeting at Hot Springs, Ark., November 20, 21, 22, and 23, 1894.

The Association is now in a more prosperous condition than ever before, and no efforts will be spared to make the meeting at Hot Springs not only the largest but the most interesting and profitable ever held. Many valuable papers by most excellent authors have already been promised.

A New Postal Regulation.—Existing postal regulations have been so amended that periodic bulletins issued by State Boards of Health shall be admitted to the mails as second-class matter and be subjected to corresponding rates of postage.

A Hospital for Tuberculous Patients, in Toronto, will probably shortly be established, a public-spirited citizen, Mr. W. J. Gage, having offered to contribute $25,000 for the purpose.

The Elms Hospital for Women, of Detroit, announces a course of fifteen lectures in connection with the work of its Training School for Nurses.

ORGANIC STRICTURE OF THE URETHRA.[1]

Methods of Treatment Recommended, with Indications for their Employment.

BY ORVILLE HORWITZ, B.S., M.D.,
OF PHILADELPHIA:
CLINICAL PROFESSOR OF GENITO-URINARY DISEASES IN JEFFERSON MEDICAL COLLEGE, SURGEON TO THE PHILADELPHIA HOSPITAL, ETC.

IN this paper it is proposed to recount only such methods of treating stricture of the urethra as are believed to be most reliable and that at the same time offer the quickest and most permanent results. There is hardly any malady about whose treatment surgeons differ more widely than that of urethral stricture. Many authorities recommend some one of the various methods of dilatation, and condemn all other forms of treatment; others advocate the cutting-operations; and, again some make use of both dilatation and cutting.

At the very outset the patient must be carefully examined, to determine the position, caliber, resiliency, existing irritability of the stricture, and whether there be one or more. The condition of the bladder and kidneys must be ascertained, and a microscopic and chemic examination of the urine must be made to determine whether casts, pus, mucus or blood be present, and whether the urine contain albumin or sugar; also the quantity of urea present, and the quantity of urine passed during twenty-four hours.

The various methods employed for the eradication of stricture are gradual dilatation, continuous dilatation, modified rapid dilatation (which is a modification of the method known as divulsion), internal urethrotomy, dilating internal urethrotomy, dilating internal and external perineal urethrotomy, external perineal urethrotomy with a guide, and external urethrotomy without a guide, more generally known as perineal section.

Gradual dilatation is the treatment usually pursued for the relief of stricture, and is by far the safest method that can be used, as death has never been known to follow its employment. In soft, recent strictures, the number of permanent cures resulting from gradual dilatation compares favorably with that of those treated by internal urethrotomy, without incurring the risk attendant upon the latter operation.

[1] Read before the Medical Society of the State of Pennsylvania.

To perform gradual dilatation the character, position, and caliber of the stricture should be determined by means of a bougie à boule. The operator should begin, when the caliber of the stricture is large, with a conical steel bougie one or two sizes below the diameter of the coarctation, as there is usually associated with this condition more or less hyperesthesia of the urethra, and the onward progress of an instrument large enough to fill or distend the stricture gives rise to great pain, which causes more or less spasm, interfering with the advance of the bougie. The structures in the neighborhood of the obstruction are likely to be congested, chronically inflamed, and softened; if there is much distention the mucous membrane is easily lacerated, and more or less blood flows, and there is pain after micturition. In rare cases urine is absorbed into the system in consequence of abrasion or laceration, giving rise to urinary fever; but by beginning with a bougie smaller in diameter than the caliber of the stricture this complication is frequently avoided. The confidence of the patient is gained by the instrument producing but little pain, and after the bougie has been passed a few times much more rapid progress can be made than when force is used.

The rule that I have adopted is to increase the size of the instrument as the pain of insertion diminishes and as the amount of blood following the introduction is lessened in amount, or ceases. The instrument should not be introduced more frequently than every third day, and should be immediately withdrawn.

Both the urethra and the instruments should be put in a thoroughly aseptic condition. The urethral instruments should be washed in a solution of soda, subjected to heat, and dried on an aseptic towel before being used. Over the operating-table should be arranged a receptacle to contain water, to which have been added ten grains of boric acid to each ounce, and, by means of a rubber catheter, which has been sterilized by being immersed in a 1 : 1000 mercuric-chlorid solution, the urethra is irrigated, and a clean bougie that has been lubricated with an ointment composed of a dram of oil of eucalyptus, or boric acid, to the ounce of vaselin is inserted.

Palmer has shown the value of boric acid in sterilizing the urine, if administered internally when the patient is first placed under treatment. It should be given for two weeks, in doses of ten grains three times daily. Urinary fever is most

likely to occur at the beginning of the treatment, when the mucous membrane of the canal is in a condition of subacute inflammation, and somewhat softened. It is by employing boric acid that this condition is as a rule avoided.

Examination of the urethra by means of the endoscope will show how rapidly the inflammatory symptoms disappear in the neighborhood of the stricture when partial dilatation has been accomplished. This change possibly accounts for the rapid amelioration of the local symptoms of which patients so frequently complain; it takes place even after the instrument has been passed but a few times and the caliber of the urethra has not yet been restored.

The length of time that the treatment should be continued will vary with the condition of the obstruction to be overcome. If the stricture is extensive, about three months will be required to restore the urethra to its normal size. During this time the patient is to be instructed in the use of the instrument, which he should be directed to pass twice a week for a period of two months longer, after which he must use it once a week for a similar period, then once in two weeks, and finally once a month. The treatment may then be stopped, the individual being directed to return to the use of the instrument whenever there is an indication that recurrence is taking place.

By the method here outlined, of faithfully employing the instrument when necessary, the patient can always keep the urethra clear of obstruction, and need suffer from no further urinary difficulty. In cases of stricture of very small caliber a much longer time than the period here indicated will be required to bring about permanently good results.

Gradual dilatation may be employed for years, with every advantage to the patient, no symptom of obstruction making its appearance, and no indication of trouble from the prolonged use of the bougie.

When this method is pursued with recent strictures they frequently altogether disappear, and give no further trouble. Under such circumstances the further use of the instrument may be dispensed with.

Gradual dilatation is indicated in all cases of recent dilatable stricture in any portion of the urethra, and in all cases in which the stricture is not irritable, resilient or nodular. Firm, well-organized bands, situated within from three-and-a-half to four inches of the meatus require other measures for their relief.

In cases of diabetes and advanced disease of the kidneys gradual dilatation is far safer than any other method of treatment. This is likewise the case in those suffering from debility, disease of the heart, in persons who are broken down in health, or in the very old, especially if there co-exist chronic urinary fever.

In many instances I would have advised in favor of one of the cutting operations instead of dilatation, had not ample experience taught me that in case of a well-organized stricture urethrotomy is followed by recontraction about as frequently as dilatation, the patient at the same time running the great hazard that always follows a cutting-operation, with very little if any better chance of permanent benefit in his favor.

It cannot be denied that every urethrotomy is attended with more or less risk to the patient, whilst dilatation is perfectly safe; moreover, the farther the division of the stricture is made from the meatus the greater will be danger from the operation.

I have seen, in the practice of one of the most distinguished surgeons of this city, death follow from simple division of the meatus. This unfortunate result was due to shock, and occurred four hours after the operation, in spite of every effort to avert the catastrophe. Even in the hands of the most experienced operators the death-rate from internal urethrotomy is two in every hundred cases.

Taking the dangers of the cutting-methods into consideration, and also the fact that they are rarely followed by permanent results, it would seem to be obligatory on the part of the surgeon to give the uninformed the option of the safest course. If the cure from the cutting-operations were radical, and if the strictures did not recontract in a large percentage of cases, it would doubtless be the duty of the practitioner to allow the patient to run the risk of urethrotomy; but when we are assured that the result is by no means certain by any method now employed, we should not hesitate to recommend a course that, whilst it has its disadvantages, yet relieves the symptoms due to obstruction, and is absolutely safe.

Continuous dilatation. In resorting to continuous dilatation, the surgeon should begin with a very small instrument, a filiform bougie being usually employed. This must be allowed to remain *in situ* for three days, when, as a result of continuous pressure, the stricture relaxes sufficiently to allow of the introduction of a larger instrument. As a rule, the tunnelled catheter is the instrument to be used; this is passed over the whalebone and through the obstruction into the bladder. After this the surgeon is free to deal with the stricture in any manner that he may prefer.

There are two conditions under which this method of treatment is applicable: First, when there exists a stricture of small caliber, usually situated in the membranous portion of the canal, and generally accompanied by retention of urine; secondly, when,

although the stricture is tight, the patient is enabled to pass urine with sufficient ease to allow him to be prepared for a radical operation.

In the first instance, when a filiform has been inserted, a Gouley tunnelled catheter should, if possible, be threaded over the whalebone, passed through the obstruction, and the urine withdrawn. Should the effort to pass the catheter be unsuccessful the filiform bougie should be fastened so that it cannot come out of the urethra; if the symptoms are urgent the bladder must be aspirated. If the viscus is not overdistended the patient should be given half a grain of morphin and immersed in a hot bath, when he will have but little further trouble in passing his urine. The stricture can then be treated as the surgeon may deem most expedient.

Under the second condition continuous dilatation is employed simply to enable the operator to overcome the coarctation by the use of either gradual or modified rapid dilatation, or to enable him to enlarge the stricture sufficiently to pass a Syme's staff and thus facilitate the performance of external perineal urethrotomy, should this operation be indicated.

The failure of many practitioners to use filiform bougies successfully depends on various causes: these instruments, as sold in the shops, are more often than otherwise worthless; they are too stiff, not well rounded, and do not terminate in a proper neck, and are generally too large to be threaded over the smaller-sized catheters. The surgeon should make his own filiform bougies; a dozen properly constructed will, with ordinary care, last through several years of active practice. An important rule to follow is to employ the filiform before another bougie, a catheter, or any other instrument has been introduced into the urethra. If an instrument has been previously used it is of very little avail to attempt to pass a filiform, as failure will generally result. The operator must not be sparing of his time in these cases, as infinite patience is a necessary element of success.

It is well first to distend the canal by gently injecting a syringeful of carbolized oil before inserting the filiform, which has been rendered aseptic, and which is to be introduced into the meatus and passed slowly down to the obstruction, while at the same time the patient's face is carefully watched for the slightest expression of pain, which indicates that the onward passage of the filiform must cease. The slightest impediment to the passage of the bougie should warn the operator that he has proceeded far enough with the instrument, when a second should be introduced in the same manner, and the process thus repeated until six or eight whalebones have been inserted, when the operator very gently tries each in turn to see if he can find the opening in the obstruction; beginning on the left and passing to the right side of the patient, the surgeon naturally tending to work toward himself.

If the stricture be eccentric the opening will probably be found by this manipulation, when the instrument will glide through the contraction with little or no pain; and without force being required it will pass into the bladder and will be freely movable in the urethra.

These instruments are frequently made with a spiral twist at the end, on the supposition that the physician can more readily pass such a one should the stricture be eccentric. I have never had any use for a filiform of this description, as I have in every instance had perfect success with the straight instrument.

In order to successfully insert a tunnelled catheter over the filiform and through the stricture the catheter should be gently passed down to the obstruction, then transferred from the right to the left hand, and whilst the right hand puts the penis on the stretch the filiform is to be withdrawn about a quarter of an inch, and then both the filiform and the tunnelled catheter are to be carried together through the coarctation. This procedure prevents the catheter from cutting the filiform in two and assists in guiding the instrument through the obstruction.

This method of treatment is of great value as an adjunct to the employment of more radical measures. It is of service in relieving retention of urine due to strictures of small caliber, in preparing the canal for gradual or modified rapid dilatation, and in permitting the passage of a staff for external perineal urethrotomy.

If a stricture exists in the neighborhood of the bulbous or membranous portion of the canal, and is neither irritable, resilient, nor nodular, the employment of continuous dilatation should be followed by the gradual method, and if this is not practicable modified rapid dilatation is strongly recommended.

By *modified rapid dilatation* is meant a modification of the procedure generally known as *divulsion*, by which is understood the passing of a dilator so as to rupture the constricting bands. Divulsion of a stricture by Holt's instrument is generally condemned as dangerous to life, as has been abundantly proved by a large mass of clinical testimony; nor does it offer better results than safer methods.

The operation to which I have given the name of modified rapid dilatation is not in favor with many genito-urinary surgeons. Up to this time I have operated by this method on ninety-six strictures of small caliber situated in the membranous portion of the urethra, and I have had good results in all. In one instance only did the temperature rise above 100° F.; in this case the fever was doubtless owing to the interference of the patient, who removed the

catheter on the second day, in the face of explicit directions to the contrary.

Prof. John H. Brinton, who has been an advocate of this form of operation for many years, and who has operated upon a large number of patients, has had similar results. Patients thus operated on are confined to the house but four days, at the end of which time they are allowed to go about, with directions to report to the surgeon twice a week, in order to have a full-sized bougie inserted, which they soon learn to use themselves. The treatment is to be continued as advised when speaking of gradual dilatation.

I have not observed that strictures thus treated show any greater tendency to re-contract than those in which either internal or external urethothomy has been performed, especially if dilatation is continued afterward.

To properly carry out this method of treatment the patient is to be put to bed, the urethra is washed out with a 4 per cent. solution of boric acid and an aseptic filiform bougie is passed and tied in place. The patient is then given ten grains of boric acid three times daily, and the urethra is to be daily irrigated with boric-acid solution. At the termination of the third day the patient is etherized and the urethra washed with a 1 : 20,000 mercuric-chlorid solution. The Thompson dilator is then passed over the filiform and through the obstruction, when, by means of the thumb-screw attached to the handle, the blades of the instrument are slowly and very gradually separated to a very slight degree, and after remaining in this position for one minute are again approximated.

This procedure of alternate separation and approximation of the blades of the instrument is repeated, taking care each time to separate the blades of the instrument to a somewhat greater extent, until the stricture is enlarged sufficiently to allow of the insertion of a Gross dilator, which requires that the caliber of the urethra should not be less than 18 F.

The Thompson instrument is then removed and the Gross instrument inserted. In the same gradual manner the caliber of the urethra is brought to the full size of the canal, which has previously been ascertained by means of a bougie à boule. The time occupied in carrying out this treatment should be from *twenty to thirty minutes*.

Strictures so treated are stretched rather than lacerated or torn ; this is shown by the little or no hemorrhage that follows, and on examination with the endoscope two weeks later, the walls of the urethra will be found to be smooth and not ragged, as might naturally be expected if laceration had taken place.

After the Gross instrument is removed a full-sized bougie is passed, to ascertain whether all obstruction has been removed ; if this is found to be the case the urethra should be irrigated with a 1 : 20,000 mercuric-chlorid solution and a sterilized catheter passed and tied in place ; then a small quantity of warm boric-acid solution is to be injected into the bladder. The patient is put to bed ; the urethra and bladder are to be daily irrigated with a warm boric-acid solution, and on the fourth day the instrument is removed and a full-sized bougie is passed. The patient is allowed to sit up, and may resume his duties on the following day.

This method is applicable to the treatment of filiform strictures situated in the neighborhood of the bulbous and membranous portions of the urethra, and which are neither irritable, resilient, nor nodular, and which cannot be treated by gradual dilatation. It likewise offers the best chance when time is an object, as for instance, when the individual is about to undertake a journey or is about to be married. It should not be performed in the aged, nor in those suffering from disease of the kidney, urinary fistula, or abscess of the perineum. In many cases in which the stricture was resilient, the caliber very small, and a perineal section was indicated I have employed it primarily to facilitate the passage of the grooved staff, immediately afterward performing the cutting-operation.

It would surely seem that an operation that is so free from complications, attended with so little danger to life, and which at the same time produces such favorable results, with no greater tendency to relapse than is to be encountered after other methods, is entitled to a prominent place among the resources that the surgeon possesses wherewith to overcome obstructions in the bulbous and membranous portions of the urethra.

When it is observed that in performing modified gradual dilatation the stricture is dilated gradually, and that an effort is simply made to restore the contracted portion of the canal to its normal caliber, that it is not over-dilated, and that in conjunction with the operation the strictest aseptic and antiseptic precautions are employed, it will be seen that it differs very materially from the method of divulsion, which should become obsolete.

Internal urethrotomy should be limited to well-organized strictures situated within from three-and-a-half to four inches from the meatus. If they be of such small caliber that a urethrotome cannot be passed, they should be first cut on the roof of the urethra, from before backward, by means of the Maisonneuve instrument, and the constriction should be divided on the floor of the canal by the Gross urethrotome, which, being of the shape of a bulbous bougie, locates the constricting band with great exactness. Strictures of the meatus and of the neigh-

borhood of the fossa navicularis should be divided on the floor of the urethra, especially if they give rise to reflex symptoms.

Dilating internal urethrotomy, though very thorough, is not indicated in many instances. Some of the worst obstructions with which I have met have followed it.

Its sphere of usefulness is confined to those conditions in which the stricture is well organized, of long standing, situated within three-and-a-half inches of the meatus, and is either nodular or resilient. In the latter conditions it is the only operation that offers permanent relief; but unless the patient employs the bougie in the manner recommended when treating of gradual dilatation, the coarctation will be likely to re-form.

Dilating internal urethrotomy should not be employed in a case of ordinary stricture of the penile portion of the canal, unless this be complicated in the manner already described, as the operation is likely to be followed by a curvature of the penis, which may last for a period ranging from six weeks to a year, and is, of course, a source of great mental anxiety to the individual. What is far worse, however, is that the knife of the instrument cuts so deeply that an extensive division of the muscular fibers of the urethra follows, and as a result dribbling of urine after the act of micturition takes place; as the canal is unable to expel the last drops of urine, it slowly oozes from the meatus. This condition is permanent.

If it can be avoided, dilating internal urethrotomy should not be performed on persons suffering from impotence, neurasthenia, abnormal nocturnal losses, or sexual hypochondriasis. Very naturally, the incurvation of the penis and the dribbling of the urine produce very depressing mental effects on these patients, which are difficult to overcome. When these complications exist I much prefer to rely upon internal urethrotomy by the Gross instrument. I have resorted to dilating internal urethrotomy in forty-eight cases in which the conditions indicated were present, without a single death.

Combined internal and external urethrotomy is resorted to for the relief of nodular strictures of the penile portion of the urethra and of strictures of the bulbous portion of the canal. The object in opening the membranous portion of the tube is that in cases of nodular stricture situated on the anterior portion of the urethra, and which has been divided, the parts may be put at physiologic rest, and thus the indurated tissue of which they are formed is permitted to undergo fatty degeneration, atrophy, and absorption.

I have twice performed combined internal and external urethrotomy with success; on three occasions I modified it with equally good results. The strictures were situated about two-and-a-half inches from the meatus, and were nodular, resilient, and of very small caliber. By means of the Maisonneuve instrument they were divided on the roof of the canal, and the insertion of the Otis dilating urethretome thus permitted; the constricting bands on the floor were now freely divided and the caliber of the urethra brought to its full size. A silver catheter was then passed, fastened in place, and allowed to remain *in situ* for two weeks; temporarily removing it every third day in order to sterilize it. The urethra and bladder were daily irrigated with boric-acid solution. The induration around the seat of the stricture disappeared, and the patients recovered without the necessity for complicating the cases by the addition of perineal punctures.

In *external perineal urethrotomy by means of a guide* the membranous urethra is opened, the surgeon being guided in reaching that portion of the canal by either a Syme's staff or a filiform bougie. It is employed in cases of non-dilatable, resilient, nodular strictures of small caliber, of obstructions of the canal associated with fistulæ and abscesses of the perineum, and in conjunction with internal urethrotomy performed upon some part of the penile portion of the urethra.

External perineal urethrotomy without a guide, generally known as *perineal section*, is performed when no guide of any kind can be passed through the obstruction. It is usually necessary in cases of stricture of traumatic origin, of obstructions associated with fistulæ and abscesses, and of false passages, with retention of urine. It may be performed either by carefully dissecting down upon the urethra until it is found, and then cutting through the stricture, or by resorting to the Cocks or the Wheelhouse method.

With the aid of a modification of the Wheelhouse staff which I have designed I have been enabled to very materially simplify the operation of Wheelhouse. The modified staff consists of two blades terminating at one end in the ordinary hook, like that of the Wheelhouse instrument. At the handle is a thumb-screw, by means of which the blades of the shaft may be separated. An indicator serves to show the extent to which the blades have been parted. This instrument is passed into the canal until it comes in contact with the stricture; it is then withdrawn for a distance of a quarter of an inch, when, by means of the thumb-screw, the blades are separated and the instrument is set; the urethra is thus fixed and made prominent. After the skin is divided in the median line of the perineum, the surgeon, by a single incision, opens the urethra one-fourth of an inch in front of the contraction; the blades of the instrument are then brought into apposition, and the staff is turned so that the hook

engages the upper angle of the incision. The remainder of the operation is completed in the manner recommended by Mr. Wheelhouse.

Electrolysis. Of ten cases in which I attempted to treat strictures by this means, all did badly. In most, either urethritis, prostatitis, cystitis, or epididymitis followed, and the treatment was necessarily abandoned. In those wherein these complications did not arise there was no improvement. In one only was there slight benefit, and this was due to the gradual dilatation of the coarctation produced by the electrode. This method of treatment is therefore not recommended.

SOME PRACTICAL POINTS ON ETHER-ANESTHESIA.[1]

BY WILLIAM D. PORTER, A.M., M.D.;
OF CINCINNATI, OHIO.

IT is not the purpose of this paper to discuss the mooted question as to whether chloroform or ether is the better anesthetic. Nor is it the intention to discuss the entire subject of anesthesia by ether and to review the extensive literature pertaining thereto. The object is to bring up for consideration and discussion a few practical points selected mainly from personal experience.

At the outset I wish to devote some consideration to the Trendelenburg position in so far as it bears on the danger or safety of the anesthetic. It is a resort of so much value in some cases of abdominal and pelvic surgery that it will be permanently adopted for those particular operations. It is well, therefore, to consider in what manner the phenomena of anesthesia are modified by this position. At first thought it might seem to be the ideal position. Prompt lowering of the head is one of the measures generally recommended in treating cases in which dangerous shock results from the anesthetic. But it is one thing to use the position temporarily to supply blood to the nerve-centers, and quite another thing to adopt the position throughout the operation.

The experiments of Hare on the rabbit are instructive in this connection. When the anesthetized rabbit is placed in a position simulating that of Trendelenburg, there is such marked respiratory failure that death soon follows. This is due to the pressure of the abdominal contents on the diaphragm. We do not get such effects in man, probably because his abdominal organs are relatively small, and because his thorax is not nearly so conical as that of the rabbit. Still, it is well to watch the action of the diaphragm with unusual care when the patient is in this position. My experience leads me to believe that the position entails but slight additional dangers, provided the table be properly constructed. As usually constructed, the middle portion is so arranged that it can be raised into a double inclined plane. One plane supports the legs of the patient and the other supports the thighs and body, while the head rests on the horizontal portion of the table, thus forcing the shoulders into the angle and flexing the head on the chest.

I have seen dangerous interference with the respiration result from this faulty position. The thighs, body, and head should rest on a single inclined plane, which should be about four feet in length. In this posture the head assumes a position of slight extension, thus facilitating respiration. The body should be prevented from slipping down the incline by securing the legs or feet. The plan of using hooks against which the shoulders rest is a faulty one, as they interfere with the free action of the chest-muscles.

Coming now to the administration of ether, we at once meet with an objectionable feature that cannot be entirely eliminated, viz., the disagreeable sensations of the patient, which usually begin with the first inhalation and continue up to the point when consciousness is lost. These sensations are due to two factors. The irritation of throat and larynx is caused directly by the ether-vapor. The sense of impending suffocation is due to an asphyxial element caused either by holding the breath or by breathing the same air over and over again, or by both.

There is a great diversity of opinion as to the time that should be consumed in producing full anesthesia. Appliances have been used for insuring such rapid generation of ether-vapor that complete narcosis results in one or two minutes. This procedure is clearly dangerous. Reeves has demonstrated that if pure ether-vapor, in large quantity, be carried into the lungs of a dog by means of a tracheal tube, death promptly follows from failure of the heart.

Another method of very rapidly inducing anesthesia consists in causing partial asphyxiation by the almost total exclusion of fresh air. This is a popular method, and is the one generally recommended in Germany, where ether now bids fair to divide the honors with chloroform. The advocates of this plan claim that it is free from danger. It has the advantage of consuming only a small quantity of ether. It has the disadvantage of causing, as a rule, extreme distress to the patient.

By adopting five or six minutes as the average time for complete anesthesia the patient suffers little discomfort, provided that up to about the point at which consciousness is lost the open method be used, and the ether-vapor be added to the inspired

[1] Read before the Ohio State Medical Society, May 18, 1894

air in a gradual and uniform manner. After many carefully-timed observations, supplemented by subsequent inquiry as to the sensations experienced by the patient, I have adopted this rule: The amount of ether inhaled is increased from zero up to the full quantity in a period of three or four minutes. After reaching this point about two additional minutes are required.

I prefer to use the Clover Inhaler, and in the following manner: The indicator in the beginning points, of course, to zero. After a few inhalations of air the indicator is moved to allow a slight admixture of ether-vapor. Many such additional quantities are liberated at short but uniform intervals until the indicator points to F, which means that all the inspired air passes through the ether-chamber. If the ether is turned on in this slow and even manner it arouses no resistance on the part of the patient, and, with a little encouragement, his breathing will be full and regular. As already intimated, about three or four minutes are consumed in this gradual increase of the anesthetic. Consciousness is almost abolished, and the rubber bag is now inflated and applied for the remaining two or two-and-a-half minutes which intervene until anesthesia is complete. After this point I discard the bag altogether. While I regard the Clover Inhaler as valuable in producing anesthesia, I consider it far superior to all other appliances for maintaining this state.

We now come to one of the most important features of the subject. The patient is anesthetized, and the problem is how best and most safely to prolong this condition during the operation. Here it is that the greatest blunders are made, many times through ignorance, often from lack of skill and judgment. The ideal plan is to select the proper level for the anesthesia, and to constantly endeavor to keep the vacillations which necessarily occur above and below this plane within the narrowest possible limits.

The wider the departure from this plan, the more dangerous to the patient and the more disturbing to the operator. Everyone has observed instances in which the ether is pushed to profound anesthesia; then fresh air with no ether is allowed until slight resistance is noted, when the ether is again pushed almost to the danger-line. At one time the breathing is labored and stertorous to an alarming degree, and again the ether is withheld so long that vomiting may ensue, and the patient sometimes so far rallies as to make it necessary for him to be restrained until anesthesia is again rendered complete. The surgeon is annoyed, now by the resistance of the patient and now by the unnecessarily deep narcosis. The operation is prolonged and the amount of ether consumed is largely increased, thereby incurring unnecessary dangers during the operation and delaying the reaction afterward.

Fortunately it is seldom that the method is so vicious as this; but it is equally seldom that sufficient effort is made to keep the anesthesia at a constant level by continuous and carefully graduated inhalations of ether. Given in this continuous manner, the quantity of ether necessary to maintain anesthesia is surprisingly small, and it becomes less the farther the anesthesia is prolonged. In this connection it is well to remember that the reduction of bodily temperature which always accompanies the use of ether has been proved by Kapeller to vary directly with the depth of anesthesia and the amount of ether inhaled.

In desperate operations, undertaken with the idea of giving the patient the only chance of life, I believe that the result often depends as much on the careful and economic administration of ether as upon the celerity and dexterity of the operator.

There is a very important factor bearing on the quantity of ether consumed, which is entirely beyond the control of the anesthetizer, viz., the duration of the operation. Anesthesia has destroyed the necessity for the rapid and ofttimes over-hasty surgery of former times; but it has not created an excuse for the extremely deliberate and even leisurely methods sometimes adopted. Cases occur in which the patient might be enabled to endure anesthesia for a half-hour, but would succumb if the time were extended 50 or 100 per cent. Too often in fatal cases the exciting cause might be truthfully written "prolonged anesthesia."

Let us drop this digression and resume the consideration of maintaining the anesthesia at a constant level. The chief indications as to the depth of anesthesia are the conjunctival reflex, the degree of muscular relaxation, and the character of the respirations. As the changes in these symptoms indicate that the anesthesia is slightly insufficient or a little greater than necessary, the skilful anesthetist promptly increases or decreases by a slight amount the quantity of ether inhaled.

Now if the problem is complicated by the impossibility of knowing at any moment the ratio of ether-vapor inhaled, and by inability to change the ratio promptly, the solution can only be approximate—in other words, handicapped by this lack of precision, the anesthetizer is compelled to adopt a deeper level as his standard and to allow greater vacillations above and below this level. The chief value of the Clover Inhaler resides in the accurate control which it gives its manipulator over the amount of ether inhaled and the readiness with which it admits of changes in the quantity. Incidentally the ether-chamber is so constructed that the surface of vaporization is constant, whether it

contains little or much ether; consequently in a constant temperature the rate of evaporation is uniform. My object in dispensing with the rubber-bag is to avoid rebreathing of air. Buxton, one of the best authorities, strongly urges the superiority of this inhaler. He seeks to avoid the danger of the asphyxial element by entirely removing the inhaler after every fifth or sixth inhalation. One of the strongest claims made for the bag is that by furnishing warm air to the patient it lessens the danger to the lungs. This danger is equally well averted by keeping the air of the room warm. In fact, unless the room is warm, the evaporation is not sufficiently rapid to keep the patient properly anesthetized without the use of the bag.

In the next place I would call attention to a symptom which I always regard with apprehension. There is a point in the induction of ether-narcosis at which there is generally some muscular rigidity. This is, as a rule, but temporary. Occasionally it becomes intense, and persists after the abolishment of the corneal reflex. It is unnecessary to say that this is a condition of real danger; but in several instances I have seen a still more dangerous condition supervene. I have seen three cases in which death seemed imminent, and in each this condition of rigidity was followed by extreme muscular flaccidity and dangerous respiratory failure. Probably this state of affairs was due to some peculiar effect of the ether upon the muscle-fibers, causing over-stimulation, followed by extreme relaxation. Three cases are too few to justify reliable conclusions, and the supposed relation of cause and effect may have been merely coincident.

The final consideration is the importance of having a hot room in which to administer ether. The statement has been made that the inhalation of ether always tends to lower the temperature of the body. Let us for a moment consider the factors that cause lowering of temperature. The muscular system of the patient is at rest. It is often impossible for him to be more than thinly clad, and moreover a considerable portion of his surface may be moistened with water or other fluid, the evaporation of which chills him. If he were not anesthetized he would require, under these circumstances, a temperature of about 80° F. to make him comfortable. Other factors come into play when the ether is administered. The first effect of the anesthetic is to stimulate the circulation and drive an unusually large quantity of blood into the skin. This means rapid radiation of heat. Often the surface is bathed in perspiration, and the evaporation results in still further abstraction of heat. The evaporation of the ether reduces the inspired air to a low temperature. So we have unusual forces abstracting heat, not only from the surface of the body but also from the interior—even from the blood-current itself. On the other hand the economy is still further embarassed by diminished oxidation.

The lowering of temperature has a threefold bearing, increasing the danger of shock, increasing the danger to the lungs, and increasing the danger to the kidneys. Tait records an observation made years ago showing the effect of ether on the kidneys. The case was one of urinary fistula in which a ureter had become imbedded in the cervix. From a point on the infravaginal portion of the cervix the urine could be seen dropping as it was emptied from the ureter. The patient was anesthetized by ether in order that the fistula might be closed. After full anesthesia, when the operator was about to proceed he was unable to find the fistulous opening, as the urine had ceased to drop. After several days the attempt was again made, with the same result. A third time the attempt was made, using chloroform as the anesthetic, when there was no trouble. It is a common observation that little urine is excreted for some hours after ether-narcosis, though the blood-pressure is often increased. Of course ether should not be administered to one who has diseased kidneys. And it is well to be certain not only that the kidneys are sound, but also that they are doing their work well. A few days' delay, to get the kidneys in good working order by the use of diuretics, is often a matter of importance that is generally overlooked.

The danger of bronchitis is due to the tendency of the cold vapor to freeze the lungs. This can be largely averted by having the air of the room sufficiently warm. It is also dangerous to the lungs for the patient to be placed in a much cooler room immediately after the operation. The ether is eliminated largely through the lungs by evaporation from the blood-stream. In this process heat is required. If the inspired air is not sufficiently warm the heat required for the evaporation of the ether will be abstracted from the lungs.

The plan most generally adopted to secure the warmth of the patient consists in the application of heat in the form of hot water. This is not only inconvenient, but has the serious drawback of having the least utility when most needed. We must remember that the problem is really to lessen the abstraction of heat from the body. If we resort to hot water it is impossible to apply heat to more than a small area of the body. If the heat in this area is higher than that of the body the blood-current absorbs heat at this point and distributes it to other portions. As long as the circulation is good this process is well maintained. Indeed, it may be carried too far and produce heatstroke. But should a condition of shock arise, the circulation falters, and there is little or no means of dis-

tributing the heat, so that at the very moment when it is indispensable it is not available. By supplying heat in the form of hot air we have the patient enveloped in an equable temperature, and we furnish a constant supply of heat for the vaporization of the ether. In the regulation of the heat in conformity with the needs of the particular case I believe that we have the means of eliminating the two greatest dangers of ether, the danger to the lungs and the danger to the kidneys.

By the aid of a hot atmosphere I have seen ether used safely in cases of bronchitis, and I know that since adopting this method I have noticed decidedly more prompt reaction after the operation. The value of the plan was emphasized and forced on my notice in the case of a woman with an extra uterine pregnancy. She had not consented to an operation until after the third attack of pain and shock. The operation was undertaken while there was still some shock, and it was feared that this condition would be dangerously increased. The day was cold, and instructions had been given to have the room well warmed. When the operation was begun, the room had been heated to a high temperature, and as it was small it was thought unsafe to open windows. The operation was concluded with considerable discomfort to the operator and assistants. Contrary to our apprehensions, there was little shock, though free hemorrhage occurred during the operation. The idea forced itself upon us that shock had been greatly lessened by the heat of the room.

I did not adopt this suggestion on the evidence of the single case, but have tested it since in several hundred cases, and have come to the conclusion that a hot room is indispensable to the safe administration of ether. The temperature should be from 80° to 90° F., depending on the condition of the patient and the nature of the operation.

A RÉSUMÉ OF TWELVE HUNDRED EXAMINATIONS FOR LIFE-INSURANCE.

BY WILLIAM H. DUKEMAN, M.D.,
OF LOS ANGELES, CAL.

DURING the last three years I have examined over twelve hundred applicants for life-insurance. While making such examinations I made a study of each and every subject, no matter whether the applicant gave the appearance of good or poor health. Every applicant was stripped of all clothing to the skin, as far as the waist, and all were examined minutely, carefully, and systematically, according to a recognized method of physical diagnosis. A complete record was kept of every examination made.

Of the whole number, 164 were rejected, failing to pass the required standard of examination. There were, besides, 30 that were rejected by the medical directors of the respective associations on account of defective family history, from hereditary causes, or otherwise. Of these, the majority were good, sound risks.

The large number of rejections, which reach a little over 16 per cent. of the total examined, are accounted for principally as follows: Pulmonary tuberculosis, 76; heart-disease, 19; rheumatism, 14; asthma, 10; albuminuria, 11; hemorrhage from the lungs, 10; fistula in ano, 5; syphilis, 3; carcinoma, 2; renal colic, 4; hepatic colic, 2; chronic disease of the liver, 6; diabetes, 3; hernia, 3; intemperance, 7; emphysema, 3; chronic constipation, 7; chronic diarrhea, 3; and disease of the nervous system, 4. In some cases more than one cause is noted as a basis for rejection.

Among those rejected on account of their family history, although the applicant himself passed a satisfactory physical examination, the cause of rejection is noted as follows: For pulmonary tuberculosis in the family, 19; heart-disease, 6; kidney-disease, 6; carcinoma, 8; disease of the brain, 4; light weight, with a doubtful family record, 15 unknown, 15. For the last no reasons were given by the medical directors of the respective companies.

Of the whole number examined, there were 49 that had had one or more attacks of pneumonia since childhood. Of this number, 32 made complete recoveries, leaving no trace of the disease, while the remainder (17) gave evidence of more or less disease of the lungs, which was distributed as follows: In 4 the disease was *mainly* in the lower lobe of the right lung; in 3 in the lower lobe of the left lung; in 4 it extended over the greater portion of the right lung; in 2 over the greater portion of the left lung; in 1 it involved the upper lobe of the right lung; in 1 the upper lobe of the left lung; and in 2 the lower lobes of both lungs. While the lower portions of the lungs were mainly involved in 11 cases, there was, however, evidence of trouble in both apices as well.

As so many people come to California for their health it is readily understood how so large a number were rejected on account of tuberculous disease of the lungs, viz., 76.

Of this number I have noted as follows: In 14 the main trouble involved the left apex; in 20 the right apex; both lungs were involved in various places in 42. Fifty gave a history of heredity, while in the remainder (26) the disease was apparently acquired.

Of the 19 rejected on account of heart-disease, 13 presented mitral lesions, 3 aortic, and in 3 there were lesions of both valves. In 1 the apex was four inches to the right of the sternum and two inches below the line of the right nipple. In 1

there was a reduplication of sounds, two systolic to one diastolic sound, although the rhythm of the heart was preserved; the heart was displaced to the left of the normal. In most of the cases there was more or less cardiac hypertrophy. In only 7 was the heart in an abnormal position.

Of the 10 rejected on account of hemorrhage from the lungs, in 4 the hemorrhage had been recent, and there was evidence of progressive disease, while in the other 6 the hemorrhage was very slight and no evidence of disease was detected. The time that had elapsed after the hemorrhage occurred varied from four to ten years. I have also notes in which 6 applicants were approved who had had hemorrhage from the lungs more than ten years before, and have since been in good, sound health.

A notable feature in the personal history of all those having lung-disease was that they were perfectly well, except that occasionally they would state that at times they had a little indigestion and biliousness, and invariably would give negative answers to all inquiries concerning the diseases usually enumerated on the examination-blanks; a few would acknowledge having at times had a little bronchitis, but only when they should "catch cold," and a few more have a very dubious family history.

Of the 11 rejected on account of albuminuria, in 7 only did I find tube-casts; the other four seemed to be in the best of health, and have always been so. As this subject has received considerable attention of late by the profession, as regards risks for life-insurance, I believe the conclusion is that in many such cases in which no other evidence of kidney-disease exists the risks may be considered safe. While the condition may be considered a purely functional or normal and physiologic one, yet, however slight the proportion of albumin in the urine, as shown by Heller's nitric-acid test, I think it always indicates an abnormality of some kind; whether this be in the kidneys or due to faulty variations of blood-pressure elsewhere I cannot say.

Of the fourteen rejected on account of acute or inflammatory rheumatism, six had had five attacks; two had had four attacks; four had had three attacks; and two had each had one very severe attack. In eleven there were mitral lesions, and in two aortic. In only five was there deformity of the joints. While there were only fourteen rejected on account of rheumatism, I find that there were forty recorded that had one or more mild attacks.

Of the whole number examined thirty-eight had had one or more attacks of typhoid fever. Of this number four failed to pass on account of weakness of the heart's action.

Of the 1200, only forty-three were native Californians, and of this number only three were rejected, viz.: one for pulmonary tuberculosis, which was hereditary, one for repeated attacks of rheumatism, and one for weak heart due to three attacks of typhoid fever. The others (1157) were persons that came to this State either for health, wealth, or the comforts of mild climate, and were, as a whole, exclusive of those rejected, not of the most robust, sinewy, hardy, healthy constitution one finds in colder climates. Their muscles and flesh did not have that hardness and elasticity and firmness characteristic of the man of the temperate climate..

Of the 1200 I find that tuberculosis in some form existed in the families of 217; this number, however, is not the total, as many applicants could not give the cause of death of parents or grandparents, as in many cases death occurred before the birth of the applicant, or during his early life. In the majority of the 217 the results of the examination and the physique did not come up to the standard of those in whom there was no heredity of tuberculosis. Of this number I have noted that in 191 the color of the eyes was blue, while the hair was dark-brown or black in very many. In only a few was the color of the eyes gray, while the others had either brown or black eyes, with very dark hair. The lung-expansion in the majority of these came up to the standard, but on investigation I learned that a large percentage had practised taking full inhalations. In some of them the chest-expansion was greatly above the average, as a result of the long-continued practice, which in some had been carried too far, and had given rise to a harsh respiratory murmur on both inspiration and expiration, and a more or less breaking up of the air-vesicles.

The greatest expansion in all cases was seven inches. The man in whom this was present was a native of New York, six feet tall, muscular, well-built, and weighing 210 pounds. The tranquil chest measured 40 inches, on forced inspiration the circumference reached 44½, and on forced expiration 37½. The man was not an athlete, nor had he ever practised lung-expansion. The respiratory murmur was soft, breezy, and even, and the man was in every sense what one would consider a perfect specimen of health.

Of the forty-three native Californians, with but one exception the lungs were in a normal healthy condition, and the soft, breezy character of the respiratory murmur was so characteristic that in many cases I could almost foretell the nativity of the individual. The lung-expansion of these was, however, below the average, perhaps as a result of the easy-going life, especially of the Southern Californian, whose climate rather conduces to quietude, if not laziness. These facts show that great lung-expansion is not essential to constitute good, sound

lungs. Of how many came to this State for their health it was impossible to get a correct account. In the answers to questions propounded to applicants for life-insurance the good side of health is invariably given, but I should venture to state that fully one-half came here because of failing health of some kind, and whether those approved will live their expectancy of life or average time allotted by life insurance companies, time alone can tell.

The applicants varied in age from twenty years to fifty-five years. The average was a fraction less than thirty-four years.

While many of these applicants came to California for the benefit of their health, which had suffered either by sickness, constitutional weakness, or the overwork of an active business life, the question naturally arises: Did not the change of climate have a favorable effect? In many it did, but more time must elapse before it can be stated positively whether or not the benefits will permanently strengthen such weakened constitutions. The city, however, is not the place for these individuals to make their home.[1] Los Angeles is not a much healthier place for such persons to live than is Philadelphia. But in the country, in various places of California, in the mountains and at the sea-shore, where the air is aseptic, with our mild climate, and with proper care, under good medical advice as to mode of living in this climate, etc., many persons can be found whose health has apparently been permanently restored, and many more are greatly benefited for a time only.

VALVULAR DISEASE OF THE HEART AND CHRONIC RHEUMATISM.[1]

BY WILLIAM W. PENNELL, M.D.,
OF FREDERICKTOWN, OHIO.

BUT few years after entering on the practice of medicine it seemed to me that chronic rheumatism was a greater factor as a cause of heart-disease than had been pointed out by most authorities. Acting upon this idea, a rather systematic observation of such patients was instituted more than ten years ago, with the result of confirming the idea that cardiac disease was gradually developed as a complication in a large percentage of cases.

Regarding rheumatism as a diathetic malady, it is not strange that visceral entanglements should occur, especially in structures having a texture similar to that of the joints. Indeed, it is eminently proper to look upon rheumatism in any form as the expression of a diathesis or predisposition of the organism to a particular kind of inflammatory activity rather than as resulting from cold, exposure and dampness, as well as improper diet.

In the last ten years I have had every opportunity to observe the course of chronic rheumatism in a number of persons. In all, twenty-five[1] were under study, every one of the number being afflicted with chronic rheumatism from the beginning, there being no history of an attack of acute rheumatic fever. Observations were made weekly or monthly in each case. Eighteen patients gradually acquired heart-disease, seven thus far escaping. True, most of these persons were beyond middle life, and some were in the last quarter, periods in which chronic rheumatism is most likely to develop, also the period in which senile changes were to be expected as the result of a long series of years of hard labor and exposure, in addition to the gradual wane of vitality, with the consequent nutritive alterations in the circulatory system.

There is, so far as am aware, no anatomic reason why the rheumatic habit should not produce ravages in fibrous tissue, though it be located outside the articulations. Just why some should teach that the fibrous rings of the heart and the fibrous material of its valves and arteries have exemption in the chronic form of rheumatism is difficult to understand. But few authorities mention the possibility of complications of the sort; and then the cardiac disease is generally said to have its inception in the acute rheumatic attack that precedes the chronic in many individuals. Fewer still are the writers who ascribe heart-disease directly to chronic rheumatism, pure and simple; but all are willing to believe that the age of the patient at which valvular disease manifests itself has more to do with its production than any diathesis.

In my experience persons with chronic rheumatism for the most part sooner or later manifest some form of heart-disease, and the lesser number escape such a complication. Those in whom it appears being advanced in life, the cause is ascribed to senility and not to rheumatism. On the other hand, the majority of old persons that have never had rheumatism of any kind do not exhibit alterations of the heart more frequently than of any other organ or structure. And yet it seems scarcely possible for a person of seventy years with chronic rheumatism to escape without some lesion of the endocardium. Out of a great many patients affected with the acute disease it has been my fortune to see but few have pericardial or endocardial complications from a single or subsequent attack; but individuals subject to repeated or recurring seizures do for the most part become victims of heart-disease, more especially when in the interval between

[1] See article by author: "Where to Send the Consumptive in Southern California," in New York Medical Journal.

[2] Read by title before the Ohio State Medical Society, May 18, 1894.

[1] Ranging from thirty to seventy years of age.

acute invasions they suffer more or less with subacute or chronic articular inflammation.

These facts demonstrate the essentially diathetic nature of the disease, just as a case of acute pericarditis or endocarditis may be soon followed by acute articular rheumatism; or, as I have a few times seen, an individual with a chronic valvular lesion, evidently rheumatic in character, may acquire chronic rheumatism of the joints. This habit, if not hereditary, is quite readily acquired by some persons who seem to require less exposure, dietary errors, and dampness than other persons to induce an attack.

On the theory that rheumatism is the result of diathesis, it is reasonable that the same *materies morbi* which, by its presence or influence, alters the nutrition of the fibrous structure of joints, would, by constant circulation in the blood, gradually manifest itself in other fibrous tissues, especially in the heart, as this organ is unremittingly exposed to its influence.

The difference between acute and chronic rheumatism resides in the intensity and duration of the disease. They seem to be the same, modified by the patient's inherent power of resistance. Be that product of the individual peculiarity uric or lactic acid, or both, or whatever it may be, it has a predilection for fibrous and fibro-serous tissues. If one form is specific, the other is specific; the cause consisting either in the production within the body of morbid matter from interference with excretion from continued exposure to cold and wet or in the elaboration of toxins from improper food. These facts are far from establishing the specific nature of rheumatism. They more clearly demonstrate its constitutional character. The general type of the acute form is shown by the thoracic and abdominal complications that often occur, as well as keratitis and iritis, and by its affinity for the nervous system in the occasional production of chorea. So in the chronic variety. In this form the occurrence of thoracic and abdominal troubles due to a rheumatic cause are pretty well recognized.

In addition to these facts, it is reasonable to suppose that it has been the experience of other physicians, in common with myself, to have observed headaches in chronic rheumatic patients that were not due to disease of heart, liver, stomach, or kidney, but subject to the variations of barometric pressure and relievable only by anti-rheumatic treatment, dietary, sanitary and medicinal. Our experiences have, no doubt, coincided in that we have once in a while seen a case of chronic rheumatism persist for four or five years and then vanish as mysteriously as it came, leaving the patient little the worse for the visitation except for a stiff joint or so.

Our common experience is to see the gradual deterioration wrought by primary continuous chronic rheumatic disease; joints becoming weaker and stiffer; structural changes in ligaments, and capsules becoming more pronounced and accompanied by pain of variable severity, and yet the general health of the patient remain quite good, although he is unable to work and is hardly able to walk without crutch or cane. Chronic rheumatism is said to scarcely ever kill. This may be true. But it has seemed to me to do the reverse by inducing endocardial and arterial changes that result in stenosis, insufficiency or endarteritis, that indirectly do kill, or else I have had more than my share of coincidences, or am wofully shortsighted.

Complete recovery hardly ever occurs except in recent and mild cases which are removed from the conditions that feed the rheumatic habit, and thus receive permanent improvement, if not cure. Those that have had the disease for but a comparatively short time should not be discouraged with the idea of its incurability, but should rather have pointed out to them a possible means of escape, if not from the entire disease itself, at least from its ultimate consequences, by permanent arrest. For those cases that have become confirmed and intractable and have as yet shown no cardiac disturbance, as large a degree of immunity as possible should be secured against such complications. And when heart-disease has developed, its consequences should be avoided so far as they can be. In these latter cases we can secure the good effect of internal medication: namely, that directed to the cardiac complication, and that is the persistent use of digitalis.

Medicines do little good for chronic rheumatism. Its best treatment consists in massage, electricity, baths and diet. Elimination is the watchword in this disease. Massage, through its effect on the circulation favors excretion, as do baths, by stimulating the skin. The utility of diuretics and laxatives cannot be overlooked. The diet should be as nearly vegetarian as possible to preclude the introduction of toxic ptomaïns or their production within the alimentary canal. This paper is, however, not devoted to the treatment of chronic rheumatism, but rather to point out in a feeble way one of its most fearful consequences. The lesions of the heart do not differ in their symptoms from those due to other causes, and, like those arising in the acute disease, have a more favorable prognosis than those resulting from degenerative changes that are necessarily progressive.

Perhaps they are more amenable to arrestive treatment than the acute, as their growth or development is slow; but once developed to any degree they are permanent, their situation determining their gravity. If in the management of this disease these lesions could be avoided our work will not have been in vain.

CLINICAL MEMORANDA.

SOME INTERESTING SURGICAL CASES, WITH THE EXHIBITION OF AN ORIGINAL INSTRUMENT.[1]

By SCHUYLER C. GRAVES, M.D.,
of Grand Rapids, Mich.;
Visiting Surgeon to the U. B. A. Hospital and Surgeon to the Children's Home.

The cases that I have to report are: 1. Gould's extirpation of the penis, with perineal transplantation of the urethra, for malignant disease; and, 2. Phelps' operation for the cure of talipes, particularly that variety known as "talipes equino-varus congenitalis."

The instrument is a nephrectomy-clamp, devised for assistance during the operation of lumbar nephrectomy.

1. To me it has long appeared an insufficient and hence an unsurgical procedure to remove a portion of the penis for malignant disease. When we find malignancy connected with and limited to viscera elsewhere; when we find the breast, or the uterus, or the kidney, or the testicle, the subject of disease of such nature, we unhesitatingly remove the whole organ. It is best so to do; but with the penis; with an organ so fairly crowded with bloodvessels and lymph-vessels; with so many inviting nooks and crannies and pathways, where beckoning nymphs offer such warm hospitality to the individuals comprising the invading malignant horde, this procedure (extirpation) is very seldom done. It ought to have been done oftener in the past; it will be done oftener in the future.

The operation, which takes its name from Mr. Pearce Gould, of London, although it is also known as Gouley's operation (from Dr. Gouley, of New York), and which I had the pleasure of doing at St. Joseph's Hospital, Omaha, Nebraska, in June, 1893, is done as follows:

As the meatus is generally occluded, it is necessary to do a limited amputation before it can be possible to insert a sound into the urethra. Lateral tegumentary flaps of sufficient size are first made at the base of the penis; then a knitting-needle is pushed through the organ at its root (inside the flaps) and a rubber constrictor cast loosely around and below it. The penis is then cut away about one inch from the needle (on the distal side, of course), a proper-sized steel sound passed into the urethra as far as the prostate, or thereabouts, and the ligature tightened. All bleeding will now cease.

At this juncture a dissection is commenced along the rhaphe scroti, the incision deepening between the testicles, care being taken not to enter either tunica vaginalis, until the corpus spongiosum is exposed down to the scroto-perineal junction. Then the incision is continued deeply to about the center of the perineum.

At this point in the operation the urethra is entered at the peno-scrotal junction, the sound withdrawn, the corpus spongiosum dissected away from the corpora cavernosa and delivered in the perineal incision, from the bottom of which it will hang like a tail.

The corpora cavernosa are now dissected out even to their origin on the rami ischiorum. The dorsal and cavernous arteries will here need a little attention. There are two of each, but they can easily be caught and tied.

After the arrest of hemorrhage by ligature or torsion and the free use of hot water, the edges of the incision are brought together and sutured. The trailing corpus spongiosum is cut off a little more than flush and sutured *in situ*.

In disposing of this highly surgical operation, let me sum up its good qualities: 1. It is radical. 2. It is fairly easy of performance. 3. It is not particularly dangerous. 4. It concerns parts external to the triangular ligament, and, hence, does not involve the compressor urethræ muscle, thus allowing of as much urinary control as before the operation. 5. The incisions are made in the best possible fashion for subsequent drainage. 6. The outflow of urine takes place at the very bottom of the

Fig 1.

Showing absence of the penis.

Fig 2.

Showing perineal meatus.

[1] Read before the Michigan State Medical Society.

incision, thus avoiding wound-infiltration. As to bad points, I know of none.

The man on whom I operated passed his water unaided on the second day, and on the eighteenth he went to a photograph-gallery where the appended photographs (Figs. 1 and 2) were taken. One picture shows the absence of the penis, and the other the new meatus urinarius in the perineum. Eight months after the operation there was no return of the disease. The subsequent history has not been obtainable.

2. It is but a few short years since the lives of children were tortured by screw-apparatus, or more or less ineffectual work was done by subcutaneous section of tendons and fasciæ in the attempt to cure club-foot.

It is not my purpose to take up here the pathology of talipes. I wish, however, to state, most emphatically, that for all cases of congenital equino-varus in children about the age of five or under, the operation, *par excellence*, for their absolute cure, is the one which bears the name of Phelps.

This operation has its limitations. It is found wanting, as I myself have learned, in cases of long-standing, especially in the adult forms, in which osteotomies must be done; but in the young types it is all sufficient.

It consists in making a deep, free incision on the inner aspect and sole of the foot, commencing just in front of the malleolus, and cutting *everything*. Of course, a preliminary and subcutaneous section of the tendo Achillis is made.

This incision, together with forcible correction will be found sufficient, in the cases mentioned, to overcome almost any difficulty. The member, or members, should be forcibly *over-corrected* and put up in plaster, allowing the widely-gaping wound to fill with blood-clot and heal, after the method of Schede. In two weeks the casts should be removed, when much progress toward healing will have occurred. If, at the time of the operation, it is found impossible to more than correct, that is, impossible *to over-correct*—and I have seen cases in which, with all the cutting I deemed advisable, I could not do this myself—you will find that when the casts are reapplied, two weeks later, you can then bring about an over-correction. Of course, the success of this operation depends very much upon a strict observance of the laws of asepsis. The ideal, and hence the best, operation is the aseptic one; but I know that the operation will succeed even when healing by Schede's method fails to take place.

In this connection I desire it to be understood that I have made no particular mention of asepsis and antisepsis in these reports, because I have considered it unnecessary to do so. This body of the best surgical intelligence in the State of Michigan needs no reminder of what is now such an established fact.

I take pleasure in presenting photographs of a child with club-foot, taken just before and two months after a Phelps operation (Figs. 3 and 4).

3. During the course of a lumbar nephrectomy done a year or more ago I noticed that the patient was much shocked. The operation was a difficult one, and I had reached the stage at which the pedicle is to be tied. In order to do this I would have been obliged to add to my incision or to consume considerable time in securely ligating the stem. Either of these horns of the dilemma would have greatly added to the existing shock, thus very materially diminishing the patient's chances for life.

FIG. 3.

Talipes equino varus.

FIG. 4.

Result of Phelps' operation for talipes equino-varus.

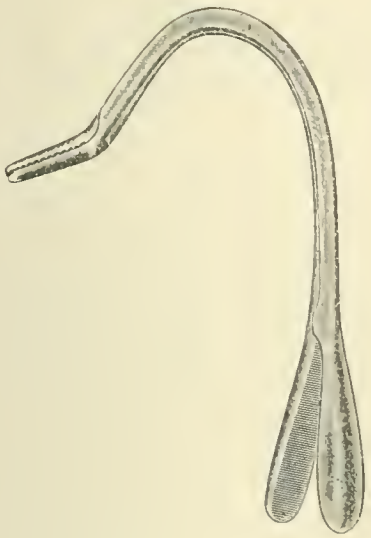
Upon the spur of the moment I seized a long pedicle clamp-forceps, guided it by sense of touch, clamped it,

and cut away the diseased mass. We put the patient to bed, and, after some hours of external and internal stimulation, she rallied, and, subsequently, underwent an uninterrupted recovery. The use of the clamp unquestionably saved the woman's life.

It was a new procedure for me. I had used the clamp in vaginal hysterectomies; but in such operations the arteries with which one has to deal are long and tortuous—they favor thrombosis. With the short, thick, able-bodied renal trunk or trunks, however, it is different. This form of clamping was a new, and, for the time being, rather an unpleasant experience; but it worked well. The clamp was removed in forty-eight hours. I immediately set about devising an instrument for use in similar emergencies, an instrument which would bring into play the new application of an old principle.

After many cadaveric nephrectomies and various modifications, the instrument was made to present the features which it now bears. (Fig. 5.)

Fig. 5.



Graves' nephrectomy-clamp.

It has the following weak points: 1. It is an instrument that will not have a very extended use, inasmuch as nephrectomies, particularly lumbar nephrectomies, are not common. 2. It causes a slough, which must, in time, come away, and thus prevents the immediate closure of the wound.

The following good points, I think, will speak for themselves: 1. It is easily, quickly, and safely applied. 2. By reason of its shape it can be included in the dressings and allowed to remain several days. 3. It is applicable to either side of the body, that is, to the pedicle of either kidney. 4. It is separable and smooth, and hence can readily be rendered aseptic.

In an emergency such as that described the instrument will, in my opinion, be found a life-saver.

The instrument can be obtained from the Detroit Pharmacal Co.

ABSENCE OF THE VAGINA, WITH HEMATOMETRA FROM RETAINED MENSES.

By JOHN C. DA COSTA, M.D.,
of Philadelphia;
Gynecologist to the Jefferson Medical College Hospital and to St. Agnes' Hospital.

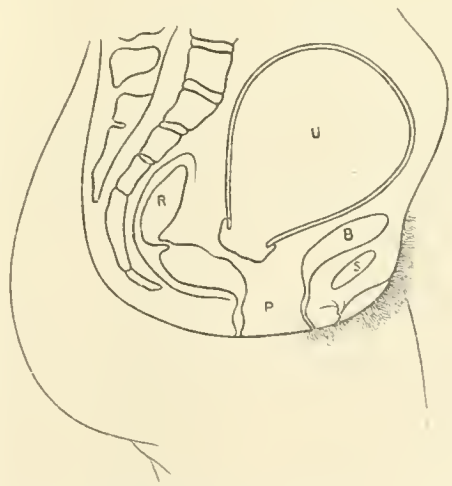
Atresia of the vagina, although not common, is still occasionally met with, but cases of absence of the vagina are very rare. The history and result of operation in the following case may, therefore, prove not uninteresting.

S. M., a negress, fourteen years old, was brought to me April 13, 1893, by her mother, who stated that the girl had been ill for some months. The girl was evidently losing flesh, and her face was expressive of intense suffering. Questioning elicited the statement that she had never menstruated and that all of her pain was in the lower part of the abdomen and pelvis. She had been perfectly well until the fall of 1892, when she was seized with severe abdominal pains, lasting three or four days, then passing away, but returning in three or four weeks. From that time she had never been free from pain, day or night, and the abdomen had been gradually increasing in size.

A look at the girl verified her statement. Her figure was that of a woman. The breasts were well filled out and the hips well rounded.

Examination of the abdomen showed the lower part to be occupied by a tumor about the size of a uterus in the fifth or sixth month of pregnancy, although the shape was different. The tumor was not the pear-shaped enlargement of pregnancy, but was nearly round, dipping well down into the pelvis; it gave evidence of fluctuation, and felt like a thick-walled cyst.

Fig. 1.



Condition before operation.

U, distended uterus. B, bladder. P, perineal body. R, rectum. S, symphysis pubis.

Examination of the vulva, or rather for the vulva, showed no vulva at all. The whole space from the urethra to the anus was a firm, fleshy mass, without any sign of either hymen or vagina. It was smooth, without any discoloration or bulging such as is seen in cases of

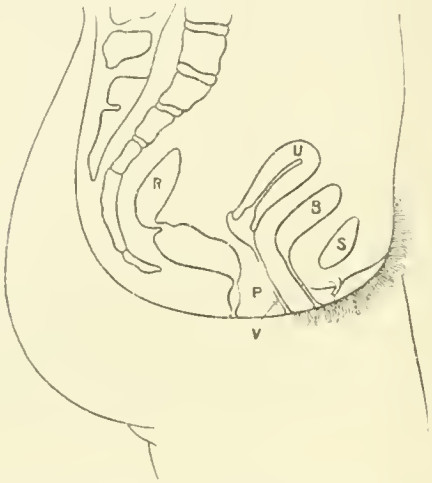
imperforate hymen, and was free from inflammation or tenderness.

Rectal examination showed, at a full finger's length from the anus, the presence of a fluctuating mass between the rectum and the bladder, and indistinctly there could be felt something suggesting a uterine cervix.

From the examination, a diagnosis was made of absence of the vagina with hematometra from retained menses.

An operation was decided on, and performed two days later, on April 17, 1893. With a large, slightly curved sound in the urethra and a finger in the rectum as guides, a good-sized incision was made transversely below and carried up parallel with the urethra, using the knife and scissors for cutting and the finger for tearing,

FIG. 2.



Condition one year after operation.

U, uterus. B, bladder. P, perineal body. R, rectum. S, symphysis pubis. V, newly made vagina.

until a distance of more than two and a quarter inches was reached, when the finger detected slight fluctuation. A good-sized trocar was then plunged through the tissues, the opening quickly enlarged with dilators, and the large mass of retained menses evacuated. Some of the matter had to be broken and detached before it could be dislodged or washed out by the antiseptic douche that was used.

Antiseptic douches were used daily for a while, and after two or three days a glass Sims plug (second size) was inserted, as the cut made was so large that the smallest plug dropped out. Larger plugs were inserted at intervals of two or three days, and in a short time the girl was discharged, well. I have seen and examined her within a month (more than a year after the operation), and she remains perfectly well, is plump, well rounded out, bright and cheerful, and menstruates regularly every month, without pain. She still wears the largest size Sims plug, and the opening shows no tendency to close.

The case presented certain peculiarities. One was the shape of the cervix. In a case of labor the cervix is obliterated, and the finger detects no cervix at all, but only a round hole in the uterus. In this case the shape of the cervix was preserved, and the part felt like a hollow cylinder, with an opening of perhaps an inch and a quarter in diameter and a wall about one-quarter of an inch thick. The cervix has never closed, as that of an ordinary uterus does after being emptied, but remains open, with an inside diameter of about an inch.

Secondly, the divided parts are not covered by healthy mucous membrane, as I hoped they would be, but appear very much like the inner wall of a cyst. The incision shows no tendency to close, as usually occurs in such cases.

It is fortunate that in view of the great accumulation and distention, no injury happened to the tubes, ovaries, or other adnexa of the uterus.

TOXICOLOGIC NOTES.

A CASE OF STRYCHNIN-POISONING.

BY LAMBERT OTT, M.D.,
OF PHILADELPHIA.

AT 11.45 A.M. an unmarried girl, twenty-five years old, took one hundred and twenty tablets, each containing gr. $\frac{1}{60}$ of strychnin sulphate. At 12.45 o'clock, or an hour later, I reached the girl and found her in severe general spasms, with clonic contractions of the extremities, extension of the head on the back with sufficient violence to throw her from a large arm-chair to the floor, where the contortions continued, their major force centering in extreme ophisthotonos, a sufficient interval being left between the body and the floor for a person to creep through. The eyes were turned up, and consciousness was apparently lost. I at once gave ether, to which the spasms yielded surprisingly soon, or else the period of relaxation had come. I then substituted chloroform, which I gave freely; also injecting $\frac{1}{4}$ gr. of morphin hypodermatically. All of these measures were required before the extreme rigidity subsided. In lifting the girl to place her on the bed her spine was found to be still rigid, but otherwise she seemed well relaxed. Dr. R. G. Stretch now joining me, we gave chloroform continuously for two hours, and every half hour $\frac{1}{4}$ gr. of morphin with $\frac{1}{50}$ gr. of atropin, only remitting the chloroform whenever the rigidity of the jaws and abdominal muscles relaxed, this being our sole guide as to the degree of narcosis necessary. All of this time the girl remained entirely unconscious, with the eyes divergent, the right pupil contracted and the left dilated, and later the right dilated and the left contracted. Her lower jaw was firmly set, the lower front teeth being nearly hidden behind the upper incisors, and only becoming visible during deep chloroform-narcosis.

After two-and-a-half hours' constant labor, thinking that the worst was over, and the general condition of the patient being good, we withdrew the chloroform temporarily, as the muscles of the jaw and abdominal walls were thoroughly relaxed, when suddenly, after a few moments' interval, there was a sharp and audible snap, caused by the teeth coming together; the muscles of the jaw and abdomen became rigid, and respiration ceased for a minute-and-a-half, with the development of deep cyanosis of the face and extremities and venous engorgement of the neck, while there was only slight rigidity of the limbs. This condition lasted so long that the appearance indicated what we supposed

was death. All seemed hopeless and useless; but as a *dernier ressort* several hypodermatic injections of brandy were made directly into the veins, and after what seemed an endless time the girl apparently relaxed in death, and the rigid jaw dropped. In a short time, however, a faint effort at inspiration was noticeable, and again, after a painful interval, there followed another faint inspiration, until gradually respiration returned, with a restoration of her natural color. In twenty minutes the breathing became stertorous, remaining so for ten minutes, when, suddenly, the lower jaw again became rigid, respiration partially ceased, some cyanosis developed, and asphyxia seemed imminent, but by pushing the chloroform danger was averted.

Then followed a period of relaxation of twenty-five minutes, when suddenly the lower jaw again became spastic and the respirations jerky, with the head drawn back; but this third attack, being much fainter than the previous two, gave us the comforting assurance that the poison had nearly spent itself, three-and-one-half hours having passed since the initiatory symptoms. After the fourth hour the girl lapsed into normal slumber, manifesting still a slight tendency to rigidity of the lower jaw, but otherwise her improvement was rapid. She regained partial consciousness at 8 o'clock in the evening, having been unconscious seven hours and forty-five minutes. A half-hour after the induction of chloroform-narcosis, in an interval of relaxation, she vomited spontaneously half a gill of mucus, which probably contained some of the strychnin not yet absorbed.

The lessons to be learned from this case are, in cases of strychnin-poisoning, to give chloroform freely, morphin and atropin in decided doses frequently, and never to trust the delusive interval of apparent relaxation until after at least four hours have passed; as long as the lower jaw and the abdominal muscles are spastic, or are relaxed and become suddenly rigid, sudden asphyxia may be induced by tonic spasms of the respiratory muscles. At no time after giving opium was there equal and simultaneous contraction of the pupils, nor in the one contracted was the narrowing permanent or "pin-head." The only time we found a weakened and nearly imperceptible pulse was during the first attack of asphyxia, when we thought her in apparent death, but during the spasms and in the intervals of relaxation the volume and frequency of the pulse were not materially altered. I was struck by the fact, however, that so grave a condition, each moment seeming about to bring death, was attended with so little change in the character of the pulse. The seven hours and more of unconsciousness were probably not due to the poison, but more likely to the chloroform and morphin, although unconsciousness set in with the first severe spasm before the anesthetic had been administered to complete relaxation. The following two days of convalescence were attended with no special drawbacks, other than the general soreness and aching, with some headache, anorexia and nervous exhaustion. On the first and second days the temperature rose to 101°, subsiding on the third day, after which followed rapid and complete recovery.

An emetic could not have been readily given when the patient was first seen, as, by reason of the severe convulsions, deglutition was impossible, and besides the patient had already absorbed the major portion of the poison ingested. Nor was it deemed wise to trust to the slow absorption by the bowel of potassium bromid and chloral, although these could have been thrown into the rectum while the patient was narcotized, and thus the first dangerous attack of asphyxia might possibly have been averted.

A CASE OF CARBOLIC-ACID POISONING; RECOVERY.

BY WALTER R. WEISER, PH.G., M.D.,
OF SPRINGFIELD, MASS.

ON the afternoon of June 16th I was called to see a strong, well-developed married woman, twenty-one years old, who had been found on the floor of her room unconscious and in complete collapse. The heart's action was weak and labored; the radial and carotid pulses imperceptible; the respirations shallow and at long intervals; perspiration profuse; the skin cold and clammy, and the pupils slightly dilated. The lips and mouth were found to be blistered, and further examination showed blisters upon the right arm and shoulder.

No one knew how long the woman had been in her room or what she had taken. I administered apomorphin hydrochlorate, gr. $\frac{1}{6}$ hypodermatically, with the result of inducing free emesis a few minutes later, the vomited matter having a distinct odor of carbolic acid. After another hypodermatic injection of strychnin sulphate, gr. $\frac{1}{20}$, I began the administration of magnesium sulphate by the mouth, alternating with olive-oil.

At this stage Dr. George D. Weston was called in consultation, and, together, we continued the treatment instituted, with occasional hypodermatic stimulation. After about four hours the patient began to regain consciousness. The reflexes were entirely abolished and there was almost complete loss of power upon the right side. She complained of no pain, but pleaded constantly for water. Urine of a blackish-green color was voided about six hours after the ingestion of the poison. The face was much swollen on the right side, and became more so during the night. On the following morning the parotid gland on the same side was found to be hard and extremely sensitive and as large as a chicken's egg. As the blisters showed that the saliva had drained from the right side of the mouth, it no doubt passed into Stensen's duct on the same side.

Upon questioning the patient, during convalescence, I learned that about seven drams of carbolic acid (95 per cent.) had been taken four hours before I first saw her. After drinking this, she says she remembers nothing until she found us working over her. Her recovery was uninterrupted. The day following the ingestion of the poison there was considerable retro-sternal and epigastric pain. The face remained swollen and painful, but the tumefaction rapidly yielded to applications of belladonna and mercurial ointments. The woman complained of numbness and tingling in the right arm and thigh, and marked anesthesia was noted; but this, with the loss of power, disappeared in the course of two or three days.

A coincidence in the case was the fact that for two years past the woman has been suffering with symptoms of cystitis, passing urine very frequently in small quantities, and always with pain. Since taking the acid the

urinary symptoms have wholly disappeared, and up to this writing there has been no recurrence. The internal after-treatment consisted in the administration of bismuth subnitrate and milk by the mouth and opium by the rectum, so that any possible favorable influence upon the vesical condition must have been due to the action of the acid in the process of its elimination.

The dilated pupils, the paralysis, the slow respiration, and the local effect on the parotid gland were of especial interest.

MEDICAL PROGRESS.

Successful Suture of the Divided Ends of a Ruptured Urethra.—ANDERSON (*Lancet*, No. 3692, p. 1372) has reported the case of a man, thirty-two years old, who in jumping backward off a bicycle alighted straddlewise on the hinder wheel. The accident was followed by much pain and great swelling and discoloration of the perineum from extravasation of blood into the tissues. There was no bleeding from the urethra, and no attempt had been made to pass urine. An endeavor was made to introduce a catheter, but without success. Ether was then administered and an incision made into the perineum in the middle line, exposing a large cavity filled with blood-clot. After clearing away the extravasation the urethra was found to be completely divided a short distance in front of the triangular ligament, the two ends being separated by a distance of about an inch. An effort was made to pass a catheter in the ordinary manner, but this was found impracticable, owing to the difficulty of fixing the vesical end of the torn canal. A soft No. 10 olivary catheter was then introduced through the wound into the upper opening and pressed on for some distance into the bladder. The other end of the instrument, which had previously been trimmed to a convenient shape, was then passed through the wound into the lower urethral opening and brought out at the external meatus. This done, the two torn margins of the canal were united by catgut sutures, and the wound was dressed with iodoform. Four days later the catheter was withdrawn, and as it had become encrusted with phosphates, the patient suffered a good deal of pain. A No. 8 silver catheter was then passed into the bladder under an anesthetic. The instrument was retained in place for ten days, the tube being kept clear by occasional injections of a solution of boric acid. After the withdrawal the evacuation of urine could be effected without difficulty, and nothing further was required beyond the occasional passage of a catheter. The man was dismissed four and a half weeks after the operation, and no tendency to the occurrence of stricture showed itself.

To Clean Soiled Slides and Cover-Glasses FUNK (*Centralblatt für Bakteriologie und Parasitenkunde*, xvi. Bd. No. 3, p. 113) recommends the following course of procedure: The slides and covers are placed for some time in oil of turpentine, the one being separated as far as possible from the other. They are then placed in a beaker and some ten or fifteen grains of potassium chlorate and an ounce of hydrochloric acid are added. The beaker is covered with a plate of glass to prevent the escape of the vapors of chlorin, and is heated over a water-bath until the covers are decolorized. The glasses are now rinsed with hot water and placed in a mixture of equal parts of pulverized soda, talcum and sifted sawdust, sufficient water being added to make a mushy mass. The beaker is heated over a water bath for half an hour and is frequently shaken. The glasses are now again rinsed with hot water and a small quantity of dilute hydrochloric or acetic acid is added. They are finally rinsed once more with hot water or with ether and alcohol, and then dried with a soft cloth.

The Treatment of Ruptured Kidney.—BRIDDON (*Annals of Surgery*, vol. xix, No. 6, p. 641) reports four cases of ruptured kidney, and gives the following indications for treatment: In cases of moderate severity the treatment will be mainly expectant; absolute rest, a bland fluid diet, and the application of ice-compresses will frequently lead to a successful issue. If an aseptic process should ensue, as indicated by rigors, sweats, and elevation of temperature, a lumbar incision should be made, and be followed by irrigation and drainage of the infected cavity. In cases in which the peritoneum is lacerated, generally as a result of more severe injuries, and in which the condition is rarely recognized until an abdominal section is made in search of the cause of the acute anemia, suspected to be due to internal hemorrhage, the indication in most cases is to supplement the section by nephrectomy.

THERAPEUTIC NOTES.

Successful Employment of Hot Baths in a Protracted Case of Cerebro-spinal Meningitis.—AUFRECHT (*Therapeutische Monatshefte*, August, 1894, p. 381) has reported a sporadic case of cerebro-spinal meningitis in a man, twenty-five years old, which failed to yield to ordinary measures, and in which a condition of somnolence had existed for ten days, and a fatal issue seemed unavoidable. The temperature was not elevated and the pulse was small and frequent, and it was decided to give the patient a daily bath at a temperature of 104° for a period of ten minutes. After the first bath some improvement was observable, and the sensorium gradually cleared, the rigidity and painfulness progressively subsided, consciousness returned, the functions of the sphincters were resumed, articulation became possible, and the internal strabismus that had been present disappeared. When, after nine baths had been given, the bathing was discontinued, the symptoms manifested a tendency to return. Three additional baths were given, after which the symptoms remained permanently in abeyance and the case went on to permanent recovery.

Potassium Permanganate for Diphtheric Angina.—At a recent meeting of the Société Médicale des Hôpitaux, CATRIN (*La Semaine Médicale*, 1894, No. 34, p. 346) reported the topical employment of potassium permanganate in the treatment of a small number of cases of diphtheric angina. A solution of 1 to 200 was employed, and the applications were made every two, three or four hours, according to the severity of the case, by means of a bit of cotton wrapped around a wooden stick. The treatment also proved efficacious in cases of angina due to streptococci.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

THE FORMATION OF NEW ORGANS TO REPLACE OTHERS DESTROYED, REMOVED, OR WANTING.

WE have already published an account of the remarkable case of Prof. J. SOLIS-COHEN in which, following total extirpation of the larynx, there was developed a structure answering the purpose of a larynx, with its vocal bands, and giving all the essential qualities of speech.[1] We have also called attention to the most noteworthy case of HUSELTON,[2] in which, as a result of attempted suicide, the epiglottis was severed from its normal connections, leaving the larynx uncovered, and in which a perfectly functional substitute was spontaneously formed *de novo* from another part of the pharyngeal wall.

Doubtless inattention to or ignorance of the possibility of such new-formations may have led to the overlooking of their frequent existence.

To these startling facts we now may add the following interesting account of an organ found in the sheep by MR. SYDNEY D. ROWLAND, B.A., of Downing College, Cambridge, England, and published in the *Journal of Anatomy and Physiology* for April, 1894:

[1] See THE NEWS, July 23, 1892, p. 98; February 18, 1893, p. 195; March 17, 1894, p. 281.

[2] See THE NEWS, June 30, 1894, p. 722.

The conditions of interest met with are the persistence of a patent foramen ovale, together with some arrangement for valvular protection, and the peculiar features of such valves.

In the specimen which first attracted attention the following was the condition:

The foramen ovale was circular in outline, and measured 2.5 cm. in diameter. The valve consisted of a membranous flap 3 cm. in length and 2 cm. in diameter, and was attached round about four-fifths of the opening, the antero-inferior one-fifth of which was free from the valve and uniformly rounded. The free edge of the valve was prolonged at intervals into fibrous cords, which were attached in groups of four or five to the auricular wall just above the line of origin in the mitral valve. These cords were not inserted directly into the wall of the auricle, but into small muscular columns, in precisely the same way as the chordæ tendineæ of the atrio-ventricular valves are inserted into the papillary muscles. The presence of muscle in these columns was proved by teased preparations stained and examined microscopically. . . .

Two other examples of this arrangement were found, but not so marked as in the specimen first observed; thus some of the cords apparently hung quite freely in the auricular cavity; these, of course, might have been attached in a similar way to the preceding during life, but as the specimen only came under examination after having been dissected by one of the members of a class, no positive statement can be made. The disposition of the valve was in all cases such as to prevent the flow of blood from the left into the right auricle; this is consistent with what we know of the relative pressure in the two auricles, that in the left being the higher.

Six other specimens were obtained exhibiting peculiarities, but as these were only modifications of one general plan, they may be described collectively. They may be divided into two classes—those in which the foramen ovale was open but small, and those in which the membrane which normally closes it was perfect, yet weak. In the first of these classes, of which there were two specimens, the aperture was about 1 cm. in diameter, and was prolonged into an oblique funnel lying in the auricular septum, as is usual in cases of open foramen ovale; but in nearly all cases distinct cords were present, connecting the free thin (left) edge of the funnel to the auricular wall. In the second class similar cords were present, but proceeding from those parts of the membrane which were weakest.

In all the cases, then, we have an arrangement of cords, or of cords and muscles, when the play of the valve is large, which would obviously take an important share in securing the efficiency of the valve by preventing reversion into the right auricle. In those cases in which there was no opening the cords would play an equally important part in strengthening the membrane, and by limiting movement, diminish the chance of the rupture by sudden shock.

From what structures normally present in the heart can we derive this arrangement of valves and cords? That the specimens form a progressive series in complexity of the same fundamental structure will, I think, be admitted. The embryonic septa naturally suggest themselves as the basis from which the valve might have

been derived, but Born has shown that the foramen ovale is an entirely new development in the atrial septum, the septum superius completely fusing with the septum intermedium. Rokitansky has described the closing of the foramen ovale at birth as taking place by the formation of a fenestrated membrane, the fenestræ of which subsequently close up.

But if this closure was imperfect the condition observed might very easily and simply result by the persistence of that portion of the membrane that lies between neighboring fenestræ, as the cords, and that part of the membrane in which the fenestræ closed completely, as the valve-flap. The funnel-condition is easily explained by supposing that the lower border of the foramen grows to meet the upper, the cords retaining their original position of insertion. . . .

The great point of interest in connection with these variations is, however, their almost exact resemblance to the condition of things met with in the atrio-ventricular valves. In both cases we have identical arrangements for preventing eversion of the valve-flaps, viz., chordæ tendineæ, and musculi papillares. But in the case of the mitral and tricuspid valves we have ample ancestral precedent to fall back upon as an explanation; such is not the case in the valves here described. It seems, then, that such a complicated and highly specialized arrangement can arise without any ancestral precedent; why, then, quote it as an explanation of the specialization in the atrio-ventricular valves, as would surely be done by anybody who was asked to explain the origin of the mechanism?

Similar results can only be produced by similar causes; we have, therefore, to look for such conditions as are common in the ontogeny of both valves as a cause which could have produced them.

It is not yet possible to say what these causes are, and the question must be left in this position. . . .

The citation of such cases at once arouses the interesting thought that a profoundly suggestive field of scientific investigation may be opening before us. We have, by the almost dogmatic insistance of the Darwinian theory, grown to consider organic structure as rigidly bound up with heredity and "ancestral precedent." Is it not possible, nay, does not any one of the foregoing cases prove that this so-called scientific truth must be modified? May not the same causes that produced a structure in the first instance and in the undifferentiated or embryonic tissue, under some circumstances again bring forth *de novo* a substitute organ in the older and more differentiated tissue?

If so, what are the laws and conditions of the new growth? When may we look for it to arise and how may we possibly stimulate or modify its production? The possibility of such neoplastic formations, benign, indeed, and in a very new sense of the word, may become less repugnant to our thought if we remember the regrowth of lost parts in many of the lower orders of animals; the substitutive or vicarious function of organs with consequent change of structure, in man, in case of lesion of the specific organs; the growth of morbid neoplasms; but especially the remarkable effects of the "natural" healing-powers in cases of peculiar or extensive injury of one or more parts. The formation of a new epiglottis is only another step or variation of the seemingly intelligent or ingenious power at work in the other processes. Many would at once say that the creation of an organ in the fetus differs from substitutive or reparative creation in the adult only in the added difficulty of differentiation of tissue in the adult.

Following the law of analogy, we would naturally suppose that the secondary or substitutive creation will be more likely to arise, more easily provoked, or aided, in proportion to the patient's youth. The older the subject the less plastic the organ-forming tissues, and in a general way the less differentiated are they. The serous, mucous, and vascular tissues, the moist structures generally, may reasonably be expected to yield more examples of this formative power than those in which the nutrition and interchange of molecular matter are hindered by their dryness, etc. Nervous structures are especially plastic, the recreation of destroyed nerve-fibrils being a well-known fact. The position of an organ or tissue may also prove a factor. The nearer to the source of nutrition, or to the centers of vital activity or nervous control, the more readily perhaps will the tissue yield to the action and influence of the reparative or recreative forces.

EDITORIAL COMMENTS.

Newspaper Medicine.—The daily press is creating quite a sensation upon the announcement of the treatment of diphtheria by means of toxins isolated from cultures of the diphtheria-bacillus. If our newspaper friends had followed the investigations that have been going on in this department of science for the last four or five years, or had taken the pains to have consulted any intelligent medical man who kept himself informed on the progress of his art, there would have been no occasion for the sensational reports that have been published, and that can do only harm, just as occurred in the instance of tuberculin. Now the essence of the recent ferment is that a number of Koch's pupils, including Behring, Kitasato, Wassermann, Brieger, and Ehrlich, have for a number of years been at work upon the subject of isolating from cultures of diphtheria-bacilli a substance that they hoped would be capable, both of conferring immunity to diphtheria and of curing the developed disease, and from reports in current medical literature it would

appear as if some measure of success had been attained in these directions. The line of work is no longer novel, and is comparable to that pursued by Pasteur these many years with hydrophobia; by Ferran, nearly ten years ago, and by Haffkine and others more recently with cholera; by Koch with tuberculosis; by E. Fraenkel with typhoid fever; by the Klemperers with pneumonia; by Tizzoni and Cattani with tetanus. The results, however, cannot yet be said to be final or conclusive, and it will be well to withhold a verdict until sufficient data have been collected on which an intelligent opinion can be based. The outlook for specific medication in the not very remote future is rather encouraging than otherwise, but there is no reason to believe that true scientific interests will be furthered by the periodic sensational discoveries of our friends, the newspapers.

The Duty on Alcohol.—It appears that somewhat unintentionally Congress in its recent tariff-legislation has removed the tax on alcohol for use in medicine and the arts. There is, however, good ground for fear that at the next session steps will be taken looking to the repeal of the clause by which this desirable change has been brought about. It is therefore incumbent upon those interested in the use of alcohol for the purposes exempted from taxation—and medical men are to no small degree concerned—to offer organized opposition to any modification of the law as it now stands.

REVIEWS.

Text-book of Abdominal Surgery. A Clinical Manual for Practitioners and Students. By Skene Keith, F.R.C.S. Ed., assisted by George E. Keith, M.B., C.M. Pp. 508. Philadelphia: J. B. Lippincott Co., 1894.

This work is of exceptional interest, as it is drawn from the personal observation of the authors. It is also based to a large extent on the life-work of Dr. Thomas Keith, "a surgeon whose early results—about 15 per cent. mortality after ovariotomy—were considered at the time so remarkable that they were described as 'doubtful,' and whose later results have been called 'phenomenal.'" We must congratulate the authors on the position they have taken against the too indiscrimiuate use of the exploratory incision, although we feel, as our means of diagnosticating abdominal complications are so limited, that we are justified in using every resource in our power for a correct solution of a difficult problem. That tapping or aspiration, which they advocate in cases of doubtful diagnosis, is not always harmless, even under the most rigid asepsis, is the opinion of our most advanced celiotomists, who do not believe that the advantage to be gained is always commensurate with the risk run. For the intraperitoneal treatment of the pedicle the authors advise "faith" in the use of the cautery, which in their opinion is safe, and which is attended by less liability to subsequent bleeding. They also assert that the great majority of surgeons use the ligature "because it requires less care and delicacy of manipulation." The chapter on appendicitis is particularly instructive, the authors taking the present stand that all apparent cases of typhlitis and perityphlitis, or nearly all, are in reality due to inflammation of the appendix; although they acknowledge that they are not prepared to say that a "simple typhlitis or perityphlitis can never exist without the appendix having been inflamed." They also advocate the repair of cervical lacerations as a cure for inflammation of the uterine appendages when this seems to have been the cause of that disease. They relate their failures as well as their successes, and, what is more, they give the therapeusis employed in each case. They believe that electricity employed according to Apostoli's method is useful in uterine fibroids, as avoiding mutilation, especially in the young, and that it may often do good in inflammations of the uterine adnexa. Altogether they have given us a well-written book, interesting not only to the general student, but to the specialist as well.

Where to Send Patients Abroad for Water-Cures and Climatic Treatment. By Thomas Linn, M.D. (The Physician's Leisure Library.) Detroit: G. S. Davis, 1894.

This little brochure of seventy-six pages gives much precise information regarding the principal health-resorts and mineral springs of Europe. The author has had many years of experience in this work, and has personally visited most of these resorts; his opinion on these points is, therefore, especially valuable. As he spends half the year in Aix-les-Bains and the remainder in Nice, his judgment of these two important health-resorts should be the best that exists.

The alphabetic index of maladies, with the names of resorts that are suitable in their treatment, will be found of great convenience. The avoidance of technical terms and the employment of simple language enable the physician to place the book in the hands of laymen about to undertake a journey abroad.

Essentials of Diseases of the Eye, Nose, and Throat. Part I. Refraction and Diseases of the Eye. By Edward Jackson, A.M., M.D., Professor of Diseases of the Eye in the Philadelphia Polyclinic, etc. Part II. Nose and Throat. By E. B. Gleason, B.S., M.D., Surgeon in Charge of the Nose, Throat, and Ear Department of the Northern Dispensary of Philadelphia. Second edition, revised; 124 illustrations. Philadelphia: W. B. Saunders, 1894.

The treatment of diseases of the eye, in connection with those of the nose and throat, is a suggestive departure in text-books. Part I of the second edition of this book is revised here and there textually, and now and then an addition has been made; but as it is confined to principles and settled facts, it has not been much enlarged. Its clearness of style and firm grasp of the subject commend it highly. Part II has been enlarged by the insertion of new matter. It is a good introduction to its subject, but perhaps advises operation too freely.

Chronic Joint-Disease. (Some Preliminary Papers.) By John Ridlon, M.A., M.D., Chicago, Ill.; and Robert Jones, F.R.S.C.E., Liverpool, Eng. Pp. 179, Index v. Chicago: C. J. Burroughs, 1894.

This volume is intended to supplement the existing text-books on orthopedic surgery. In many portions of the book an ultra-conservatism is displayed that is

scarcely in keeping with the spirit of modern surgery. On the other hand, it is stated that excisions "in children should never be performed," and that amputations "are always indicated as life-saving measures," statements which, if accepted, would prove that Fergusson and MacCormac have lived in vain. The work is not without merit, but is chiefly of value as illustrating the experience of two surgeons with the methods of a deceased practitioner of great mechanical ability.

INDEX-CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, UNITED STATES ARMY. *Authors and Subjects.* Vol. XV.: UNIVERSIDAD–VZOROFF. Washington: Government Printing Office, 1894.

THE profesion is to be congratulated upon the appearance of another volume of this most stupendous work, now nearing completion. Probably another volume will complete the catalogue proper, but a voluminous appendix will be required to include the literature that has appeared since the work was begun. Dr. Billings cannot be too highly commended for his devotion to his task, and the United States Government for its generous support.

SOCIETY PROCEEDINGS.

AMERICAN ACADEMY OF MEDICINE.

Nineteenth Annual Meeting, held at Jefferson, N. H., August 29 and 30, 1894.

THE President's Address was delivered by DR. GEO. M. GOULD, of Philadelphia, who spoke upon "Charity-organization and Medicine." He showed that the relation existing in common between the medical profession, the dependent classes, and the general community is much more intimate than is supposed. Of the dependents not one is devoid of medical relations, and of many the medical relation is the chief one. Every dependent is a patient of the community, and he is also a patient of the physician. At least as a citizen every physician has his interest in this class. The design of the paper was to get physicians to recognize the important and effective means and method of therapeutics offered by the charity-organization societies. As commonly practised charity is sin, it is selfish charity, almsgiving which doubly curses both giver and receiver. Its result is to increase, not prevent, the evil. Charity-organization aims to make benevolence scientific. Mendicity is mendacity. Mendicancy, in all its forms, is not the result, but the cause of poverty. The charity-organizer says: "1. Don't help frauds. 2. Help so as to make future help unnecessary. 3. Don't hire people to be miserable. 4. Prevent dependency." Attention was called to the fact that, first of all, it is necessary for the medical profession itself to clean house or to square itself with these principles. The hospital-abuse is a disgrace to the profession. In London, there were during 1893 in the 181 hospitals about four million out-patient visits. A similar abuse prevails in all large cities. Many of these patients were certainly able to pay something for medical services, and the younger members of the profession without hospital-positions were injured; the indiscriminate free treatment increases the evil itself, and the energies of the profession are absorbed in the gratuitous curing of disease instead of preventing it. Selfishness lies at the bottom of the evil—not benevolence, and money given to hospitals without certain provision against indiscriminate free treatment is likely to become a curse to humanity instead of a blessing. The different classes of dependents, the pauper, the orphan, the beggar, the crippled, the blind, the criminal, the epileptic, the idiotic, the insane, etc., were briefly reviewed, and the principles of treatment as advised by the charity-organization societies was considered. The evils of idleness among asylum-inmates was especially criticised. The remarkable results of the treatment of epilepsy at the Bielefeld Epileptic Colony and the Magull Home were praised, and the good that may be hoped to result from individualization of these cases, from colonization, and home-treatment was set forth. The evils of institutionalism, the growing danger of large grants of money to private institutions, the everlasting work at curative medicine and the indifference to preventive medicine were also pointed out.

DR. BAYARD HOLMES, of Chicago, presented a paper entitled "The Sources of the Defective, Dependent, and Delinquent Classes." He stated that the young child is essentially dependent for a period varying inversely with the stage of civilization in which it lives, and after a period of independence, the individual in old age becomes again dependent; these conditions must be considered normal. Independence refers to that condition of mental and physical vigor which secures a useful and productive working-power in the individual.

When, from any cause, a man cannot support himself he becomes a defective; any considerable defect produces a condition of abnormal dependency. This proposition forms the foundation for the following classification:

1. Normal dependents: children, aged.

2. Abnormal dependents: (1) defective dependents—(*a*) congenital, (*b*) acquired; (2) voluntary dependents not defective; (3) involuntary dependents not defective.

3. Delinquents: (1) defective or essential criminals; (2) accidental or educative criminals.

Dependent children constitute one of the most hopeful of all dependent classes. The non-asylum method of care adopted in Australia was considered in this connection. With the other extreme also, the aged, great abuses have crept in among the institutions established for their care. The abnormal dependents made by far the greater claim upon the State for support. Some of the cases are brought about by heredity, but by far the greater number are acquired; thus institutional or city tenement-house life is causative of the child-defective. The defects that are the result of disease appeal to medical men. Less than 20 per cent. of the blind of the United States acquire their blindness in adult life; and the same may be said of the deaf-mute. One source of the defective class has not received the attention of physicians that it ought—those made so from railway injuries. One railway trainman out of 113 was killed and one other out of every 10 was injured in 1892. And the competitive system of our shops is producing equally fearful results.

The voluntary able-bodied defective reaches that state because he finds he is paid better to tramp than to work. As to the involuntary able-bodied dependents, it is of the greatest importance that physicians should examine into the causes that lead to their development.

Of the criminal class, 45 per cent. are essential criminals, or criminals from defect; the remainder are criminals accidentally.

Criminals have increased in the United States between 1850 and 1890 a little more than twice as rapidly as the population; and most of this increase is to be found among the crimes against property.

The paper closed with the exhortation for all to study the diseases of the State that produce the conditions considered.

DR. CHARLES MCINTIRE, of Easton, Pa., read a paper upon "The Importance of the Study of the Medico-social Relations of the 'Retrogressives' to the Medical Profession."

He grouped his statements around several propositions.

1. The necessity of affording asylum-restraint or treatment to so many of the classes under discussion also makes necessary the employment of physicians. Consequently, a fair proportion of medical men obtain their livelihood, either in whole or in part, through services rendered to retrogressives.

Statistics to show the precise number could not be obtained, but one physician out of every eighty-nine in the State of New York is giving his time to the care of the insane, and is receiving a salary therefor; and at least one physician out of every twenty-five in Pennsylvania is receiving some salaried compensation for professional care of retrogressives.

2. The physicians who are receiving a salary for services given to the retrogressives are few in comparison with the number who are, in an official position, freely giving their services to the same kind of people.

There are at least 69 hospitals in Pennsylvania, and 128 other charitable institutions; to most of these medical services are rendered without any money-return.

3. Closely associated with the last proposition is the complementary statement that a large number of people are willing thus to accept this gratuitous service from the physician.

About one out of every ten of the entire population of the State of New York was a beneficiary patient either in the hospitals or dispensaries of that State in the year ending September 30, 1892.

4. As service is the highest qualification of the physician, and service is only rightly so called when it is helpful, the true solution of the problems involving the facts stated must include the helping of the person served. All plans should be judged by the results obtained from this standpoint. It was stated that the important questions growing out of these propositions were not receiving organized scientific investigation by the profession, and a hope was expressed that such a study should be made.

DR. HENRY LEFFMANN, of Philadelphia, contributed a paper on the "Relations of Food-adulterations to the Dependent Classes." He pointed out that very little trustworthy literature on this topic is obtainable. It is obvious that extended statistical study in connection with analytical data will be needed to show in detail the results of impure food, but it cannot be denied that anything that diminishes the digestibility of food or its nutritive value will be of disadvantage to those who are restricted in their means of living. In addition to the actual injury to health, it must be considered that adulteration (the term being used in its widest sense) diminishes the commercial value of food, without diminishing, materially, the cost.

Oleomargarin is an example of the damage brought about by a well-developed system of adulteration. The substance is sold to the consumers as butter and at the price of butter. The poorer classes do not get the benefit of its cheapness, but pay the price of a better article, so that independently of actual unwholesomeness, the cost of living, in proportion to the actual nourishment obtained, is increased. The presence of small amounts of metallic poisons in canned goods is also a serious matter. Dependents, defectives, and delinquents are doubtless largely instances of imperfect development, and to prevent such conditions the highest nutrition and purest food should be available.

An article upon "The Provident Dispensary in England," by DR. H. WEBSTER JONES, of London, Eng., was then read by the Secretary. He related that dispensaries were instituted in England as a response by the College of Physicians to the taunt of the Company of Apothecaries, that its members were "too proud to visit and too avaricious to bestow gratuitously" their services among the sick poor. The retort of the physicians to this was that "visits and advice profited little when medicines dispensed by the apothecaries were so inert and so exorbitant in price as to make their procurement useless even if possible." The Apothecaries' Company, organized by a separation from the grocers, not only grew in numbers, but shrewdly pushed its way into business and importance, employing many methods not to be admired to bring this about.

In 1687 the College of Physicians, in view of the admitted suffering of the poor, decided that its members should give advice "gratis," when asked, to the indigent within London and seven miles around. The apothecaries refused to coöperate, and, as a result, the first dispensary was established in 1699, in Warwick Lane, near Newgate, upon the principle of "voluntary contributions from the charitably disposed members toward a joint stock for the purpose of preparing and delivering medicines to the poor at rates near the intrinsic value."

This and the other early dispensaries were designed, according to their claim, for "the meaner sort of tradesmen, their apprentices, the servants, and the poor." To claim relief under the latter division required a certificate from a clergyman, churchwarden, or overseer of the poor of the district in which the patient lived.

In 1734 Seymour writes that the "dispensaries had been for a long time given up." It was shown that the leases expired in 1725, and were not renewed. This is the same year that Guy's Hospital was founded for the gratuitous treatment of the poor. St. George's followed in 1733, the London in 1740, and the Middlesex in 1745. These hospitals afforded advantages to those holding appointments, and caused them to use their influence for the out-patient department of these hospitals as opposed to the Provident Dispensary, especially if located near their hospital.

The first dispensary contained the germ of the Provident Dispensary: 1. Self-help. 2. Discrimination between proper and improper recipients of relief. 3. Contributory subscriptions. To these has been added some form of mutual assurance.

The next efforts were put forth in the Midland counties in 1823. The plan contemplated: 1. A list of honorary members as subscribers. 2. Free and independent members who paid for their advice. 3. Charity members, properly selected. 4. The extremely poor, depending on the parish. These institutions have continued in the "provinces" up to the present time with very little variation from the original type.

In London the tendency is toward free relief. The essayist quoted an opinion that habits of dependency were fastened upon hundreds of thousands by this indiscriminate free relief, and the London hospitals are thus converted into schools of pauperism. Twenty years' discussion of this evil has developed nothing better than the Provident Dispensary system.

A plan of such a system approved by a meeting of English gentlemen was outlined, a cardinal feature of which was, that it was to be self-supporting, and no public appeal was to be made to the contributors.

To show the extent to which free medical relief is carried in London a quotation was made from the "*Lancet* special supplement for the Metropolitan Hospital Sunday Fund," published June 2, 1894, wherein it was shown that, during the previous year 103,585 in-patients had been treated, and 3,871,290 out-patient visits had been made.

DR. J. A. SPALDING, of Portland, Maine, read a paper entitled "Is Blindness Increasing in the United States, and if so, What are the Best Means of Prevention?" He stated that no trustworthy census of the blind has ever been obtained in America. The intermingling of persons blind in one eye (as if that defect had anything to do with total blindness) with those who are blind in both eyes, and consequently the only ones who are blind, has produced endless confusion, as has been proved in the State of Maine, where personal acquaintance with one-eyed blind enrolled amongst the blind has led to curious blunders.

An effort was made by Dr. Spalding long before the last census was taken, to insist upon the census-enumerators obtaining the names of all the blind people in each district, in order that a house-to-house visitation later, by competent physicians, might obtain more perfect results. So far as ascertained, this was not done, or if done, no good has come from it.

The only way in which a correct tabulation of the blind might have been obtained having been so far neglected, we have no right to claim that blindness is on the increase, for the plain reason that we have no standard to start from. Nevertheless, the number of blind being considerable in every State, we should bend our energies to the question of prevention. Accidents might be prevented in the dangerous employments, such as stone-quarries, foundries, or machine-shops, by the use of shields of protecting glasses, but in many such establishments the overseers object to the men using such means, on the ground that they cannot see sufficiently well through them to do good work. Possibly legislation might here be useful.

A prolific cause of blindness lies in infantile ophthalmia. Legislation in that respect serves the very useful purpose of compelling many people to bring their infants so affected under early treatment, but it fails lamentably in teaching physicians how to treat them skilfully. It also fails in not compelling every midwife and every physician and nurse to use aseptic injections before the delivery of the child, and aseptic cleansing of the eyes directly after the child is born.

One of the most serious obstacles to the prevention of blindness lies in the lack of education sufficient to diagnosticate or to treat diseases of the eye by even many excellent practitioners, and a still more disheartening danger lies in the enormous abundance of partly skilled ophthalmic surgeons, who, fresh from an all too-brief post-graduate course, establish themselves as specialists in diseases of the eye in the small country towns, hoping to gain an easier living than by following the slower path of general practice. That this is no exaggeration is illustrated by the fact that Dr. Spalding had within four weeks seen two totally blind infants of about six weeks of age, and a third with extensive ulcerations of the cornea, produced by the unskilled knowledge of three such physicians in three separate localities. Even general practitioners could have done no worse.

Although the necessity of post-graduate schools is not denied, yet they ought not to grant diplomas after such brief instruction. If ophthalmology is the exact science that it is claimed to be by its practitioners, it cannot be learned in a few weeks, and everyone knows that the ophthalmoscope is not to be handled with skill in that brief time. There are too many ophthalmic surgeons who have never dissected an eye.

Dr. Spalding thought that the American Ophthalmological Society ought to raise a voice of protest against the granting of diplomas to practise as ophthalmic surgeons inside of at least three months, whilst six months would be better still.

The argument of the paper was that blindness could be better prevented by the education of well-skilled experts in diseases of the eye than by legislative means.

DR. BENJAMIN LEE, of Philadelphia, contributed a paper on "The Prevention of Blindness." In considering the question of the defective classes and the means for diminishing their numbers, it is appropriate to treat not of the absolutely blind alone but also of all who suffer from such degrees of defective or perverted vision as in any way render them less productive to society.

The State will not do its full duty in this regard until, through its sanitary authorities, it supervises the life of the individual from the cradle to the grave, and banishes every enemy of life except old age.

In the State of Pennsylvania the census of 1880 showed that blindness had increased during the previous decade more than five times more rapidly than the population. This is partly to be accounted for by the fact that the increase in population was largely due to immigration, and that the immigrants, belonging to the Slavonic and Italian races, rarely employed physicians in parturition. Hence ophthalmia neonatorum went unnoticed and unchecked. This is known to be a preventable disease. The duty of the State to prevent it by the enactment of suitable laws, and by the provision of medical relief for the destitute, and by checking its

spread in public institutions, is very clear. It is probable that one-third of the blindness now existing could thus be entirely prevented. This, however, is but half the duty of the State. Eyes originally sound are ruined in school by methods and conditions that are entirely avoidable. Among these may be noted the holding of the book too close to the eye, the use of fine print in school-books, the too-prolonged use of the eye, insufficient and badly managed lighting, use of the eyes too soon after convalescence from the exanthemata, the use of polished blackboards, irritation of the conjunctiva from chalk-dust, and many others. The State should make the office of school-director one of more responsibility and hedge it about with greater restrictions. The position should no longer be the prize of the ward-politician. The State should instruct both school-director and teachers as to their duties in regard to the health of the pupils. It would be well to have a woman on every school-board. Hours of eye-study should be diminished, and more teaching should be done by illustrated lectures. Finally, more care should be taken to stamp out the infectious diseases which so often leave impairment of vision as their sequel.

The State has a very definite and positive duty, not only for the prevention of the increase of this large class of defectives, but for the absolute abolition of one of its divisions and the notable diminution of all.

Dr. Lucien Howe, of Buffalo, N. Y., next read an article on "The Present Condition of Legislation for the Prevention of Blindness." He contended that with ophthalmia neonatorum, the cause of one-fifth of the blindness found in our asylums, the need of precautionary measures is only too apparent. Moreover, the loss of eyesight from this disease is preventable in the very large majority of cases if treatment is begun early enough. A delay of even a few hours may condemn the helpless child to a life of blindness. Hence the effort instituted by the New York State Medical Society in 1891, and continued by the American Medical Association in 1893, to secure legislation throughout the United States which should direct that infants presenting symptoms of ophthalmia neonatorum be placed at once under the care of a competent physician, with penalties for failure to do so. New York passed such a law in 1891, and since then similar legislation has been secured in Maine, Rhode Island, Minnesota, Ohio, and Maryland within the past year also. In Louisiana such a measure passed one house of the legislature, and in Illinois, Indiana, New Jersey, and North Carolina committees have been appointed by the State Medical Societies to take up the work. At recent meetings of the State Societies of Pennsylvania and Iowa strong resolutions were adopted in favor of legislative action, and in Alabama, Arkansas, California, Colorado, Connecticut, Georgia, Kansas, Kentucky, Michigan, Missouri, Nebraska, South Carolina, Tennessee, Vermont, Washington, and West Virginia, leading ophthalmologists have expressed their readiness to coöperate in the effort to secure such a measure in their respective States. The prospects, therefore, may be considered good for a quite general enactment of such legislation, and, it may be hoped, in consequence, with a material check upon the ravages of ophthalmia neonatorum.

Dr. Helen C. Putnam, of Providence, R. I., read a paper on "Physical Training as a Reformative Agent." She classified the causes of crime as cosmic, biologic, and social. Criminals are classified as: (1) Criminals by passion, a solitary crime occurring in a life of integrity; (2) recidivists, subdivided into criminals having a tendency to insanity, alcoholism, epilepsy; criminals by environment, either occasional or habitual; criminals in any environment. It is within the limits of the uncompleted attempt of anthropology to discover a criminal type to say that the criminal is of a low organic structure, and of a low level of intellection, suggesting the precocious astuteness of some children, savages, idiots, animals. His mental and moral anomalies exist in a rudimentary state in normal children and adults. Modern criminology theoretically and statistics practically demonstrate the futility of punishment in curing or preventing this social disease. The problem of crime is one of development and education. The ideal of institutions for criminals should be to return to society citizens trained to become useful members. Pioneer reformatories are introducing methods to educate mentally, develop morally, and equip with marketable skill to earn an honest livelihood. Dr. Wey, of the New York State Reformatory, has proved the need of physical treatment in upbuilding citizens from vitiated material. He assigns to the gymnasium dullards, certain of the semi-invalided, malingerers, the very nervous, boys in a sluggish or debilitated condition. Some subjects of experiment had had school, industrial and military training in the reformatory for one or two years, with no "appreciable progress." With these classes of criminals results are more satisfactory than those obtained from any other method. The aimless, shuffling gait, and the ox-like bearing give way to erect carriage, bright eyes, keener mental action, and greater alertness in the work-shop; the moral tone improves, and anti-social instincts and physical insensibilities disappear, both being characteristic of the criminal, and the latter being the basis of his "psychical analgesia"—the most fundamental peculiarity; 77 per cent. are recruited from the indifferent pupils of our public schools. The "tiny eye and tongue and pen-wagging muscle" are not the only avenues of approach to centers of cerebral activity, as Dr. Wey's work shows, under the greater difficulties of age and criminal tendencies. Physical training in reformatories and colleges is beginning at the wrong end. Gymnasia for adults are customarily under the direction of physicians. That the more impressionable frame and condition of children may benefit, it is no less necessary that there be school-physicians to guide these early formative and reformative attempts to successful issue. In Paris one hundred and fifty physicians are appointed to the public schools.

Dr. George G. Hopkins, of Brooklyn, N. Y., then read a paper upon "The Evolution of Surgery." He noted that the first dawn of the science of surgery is discovered among the Aryans; the earliest records being among the writings of the Hindu Brahmins, from 2000 to 3000 years before Christ. It may be inferred, from the fact that these books prohibit human dissections, that dissection of the human body was practised earlier. The Vaidya, or medical students, were instructed by a Garu as to the best means for "aiding the wounded and deformed." The period of study was seven years. Not more than twenty were permitted to attach themselves

to one instructor at one time; the teaching was oral and clinical. They were instructed in operations on the bladder, the eye, the ear, and the nose, and the treatment of deformities, and, we may infer, in other operations as well.

The Buddhist monarch Asoka, in 500 B.C., caused an edict to be inscribed on the native rock at Gazerat directing that hospitals be established on all the highways of his kingdom. These were to be supplied not only with a resident physician, but were to have a resident surgeon as well. The Buddhists did not invent anything, but readily absorbed the learning of the Brahmins. Nearchus states that Alexander, in his invasion of India, found the Hindoo physicians far more skilful than the Greek, and it is probable that all the medical knowledge of the Arabians was derived from India, and many think that Greece learned from Arabia.

Hippocrates, denominated the "father of medicine," must have derived much of his knowledge from earlier writers. His "bath" embodies the sentiments subscribed to by the Hindoo student two thousand years before his day. He gives many surgical truisms in his third book, besides writing several distinctly surgical books. In the reduction of many dislocations we have not to this day improved upon the methods of Hippocrates.

Seventy-five years later Aristotle contributed to the literature of anatomy, in many instances with the study of surgery in view. Herophilus, of Alexandria, was an anatomist of great ability. He practised dissections on the human body; upon the living as well as the dead, criminals being given him for the former purpose. The names of many anatomic parts in our present nomenclature were of his selection. The burning of the Alexandrian Library was a great blow to the progress of surgery.

Medical and surgical learning next centered in Rome. Aulus Cornelius Celsus flourished there in the first century of the present era. He combined the teachings of Hippocrates and those of the Alexandrian school. Mages, a surgeon of Rome at the time of Celsus, invented a double cutting gorget for incising the neck of the blader in the operation for stone.

Galen, 130 A.D., seems rather to have been a compiler and selector of other men's ideas than an originator, and in this he was more useful to the human race than many an originator. His works furnished the material for the text-books for 1200 years. He advised the ligature of arteries in severe hemorrhages. The new Alexandrian Library, which arose on the ashes of the old, in 640 A.D. gave to the Saracens, who captured the city, many works on medicine which were translated into the Arabic, taking the light back to the East, while the Occident lay in darkness for 900 years. Rhazes was the greatest of the Saracen surgeons. A knowledge of surgery found its way into Europe through the Moorish occupation of Spain.

Ambroise Paré, the father of modern surgery, was born in 1517. He rediscovered the use of the ligature, and so made surgical science possible. It required 200 years for the profession generally to accept his teachings.

The discovery of anesthesia opened the way for the development of modern surgery. McDowell's ovariotomy; Sir J. Y. Simpson's discovery of acupressure; J. Marion Sims' operation for vesico-vaginal fistula; Amusat's device of torsion of the arteries; Pasteur's careful studies, opposing autogenesis, are all footprints of the march of surgery during the present century, and lead up to a period which was to bring forth a man destined to revolutionize the whole practice of surgery. Joseph Lister will ever be hailed as one of the greatest surgical geniuses the world has ever seen.

A vast field of remedial surgery has been opened up which, previous to the time of anesthetics and antiseptics, was a *terra incognita*.

It seems hardly possible that the author could have penned the following words in his maiden medical paper in 1871: "We may hope that the day is not far distant when union by first intention will not be an uncommon occurrence."

DR. CHARLES MCINTIRE then read the "Report of the Committee on the Comparative Value of Academic Degrees." This report dealt first with that portion of the last report of President Eliot, of Harvard University, relating to the position of the A.B. degree, in which he shows that the other degrees are gradually being given to a proportionately greater number, and "are rapidly winning their way to public consideration and the respect of educated men." This, with the increased efficiency of the secondary schools and the greater demands of the professional schools, was jeopardizing the traditional four-years' course, leading to the A.B degree. In reviewing these statements, it was suggested that the Academy should be on the *qui vive* to learn every change in the educational processes and adapt itself always to the present condition.

A considerable part of the report was occupied with an account of the efforts of the Board of Regents of the University of the State of New York, looking to the elevation of the standard for entrance into the professional schools. Their present aim is to make a high-school education the minimum qualification. A plan of this kind, by which in gradually increasing conditions the students who would graduate in 1900 will have a high-school education, has been adopted by the dental schools, and the Regents are endeavoring to have the medical schools adopt the same plan. The report expressed the opinion that this was the least that the medical schools could do.

The action of the Association of American Medical Colleges in raising both the standard for entrance and increasing the length of the course leading to the degree of M.D., was noticed and commended. The report closed by calling attention to the greater educational power of the courses in our medical schools than they possessed a few years ago. This should result in more thoroughly educating the physician.

DR. J. M. MYER, of Danville, Ky., read a paper on "The Qualifications of the Physician." He maintained that the physician should have a foundation of good common sense and a thorough elementary education, followed by a classical training; the A.B. should be a prerequisite to entrance upon the study of medicine. Of the moral tone of the man there should be no question.

DR. ROBERT LOWRY SIBBET, of Carlisle, Pa., read a paper on "The Work of Our Academy."

The following resolutions were unanimously indorsed by the Academy:

Whereas, The abuse of medical charities, to which the attention of the American Academy of Medicine has been so forcibly drawn by the President in his opening address, is an evil to which the medical profession should not close its eyes; therefore,

Resolved, That the participation of physicians in the movement toward charity-organization is earnestly urged as the most efficient means of limiting the indiscriminate and injurious gratuitous bestowment of medical services.

Whereas, Inflammation of the eyes in the newly born produces defective vision or blindness, which seriously impairs the productiveness of the individual; and

Whereas, Medical experience shows that nearly all of these cases are preventable or curable, it becomes the duty of physicians everywhere to further legislation which promises to prevent this disastrous inflammation;

Resolved, Therefore, that the American Academy of Medicine unanimously favors legislation looking to the prevention of blindness amongst the newly born, and urges all physicians to exhaust every means to bring about such prevention in the hope of ultimately extinguishing the encroachments of blindness from this cause amongst future members of the State.

Whereas, Many defects of vision not amounting to blindness, but seriously impairing the usefulness of the individual have been proved to be caused by improper methods of study and defective arrangements in school-buildings; therefore,

Resolved, That physicians should use their best efforts to secure the appointment of intelligent and educated persons of both sexes on school-boards, and should make it their duty to instruct such boards in regard to the proper distribution of light in school-rooms; the adjustment of seats to desks; the apportionment of hours of study and other points conducive to the hygiene of the eyes.

Whereas, The consideration of dependents, defectives, and delinquents brings the conclusion that their numbers can be decreased by proper care of the individual in childhood and youth; therefore

Resolved, That the health of children under the conditions and requirements of public educational institutions should receive far greater consideration than it has received up to the present time; and as none but physicians are competent to diagnosticate the often obscure tendencies and abnormalities obtaining in these early years, the office of school-physician should be instituted in connection with every public school, and physicians should be upon all public school-boards, the duties of such officers being concerned with the sanitary conditions of buildings, the instruction in hygiene, personal, household, and public, and the individual physical condition of the pupils.

Whereas, The true benefit from a prolonged course of medical instruction, in which laboratory-practice has so prominent a part, can only be obtained by a mind trained to study.

Resolved, That the American Academy of Medicine congratulates the Board of Regents of the University of New York upon their efforts to secure at least a high-school education for every candidate for a medical course, and expresses the wish that they will persevere in their efforts until they are crowned with success.

Resolved, That the Academy commends the action of the dental schools of that State, and urges the medical schools to adopt the same very moderate minimum entrance qualification by the gradual increase as suggested.

The officers elected for the ensuing year are:

President—J. McF. Gaston, of Atlanta, Ga.

Vice-Presidents—Rufus P. Lincoln, of New York City; William T. Smith, of Hanover, N. H.; Helen C. Putnam, of Providence, R. I.; Victor C. Vaughan, of Ann Arbor, Mich.

Secretary and Treasurer—Charles McIntire, of Easton, Pa.

Assistant Secretary—Edgar Moore Green, of Easton, Pa.

Chairman of Committee of Arrangements—C. C. Bombaugh, of Baltimore, Md.

The next meeting of the Academy is to be held at Baltimore at the time of meeting of the American Medical Association.

NEWS ITEMS.

Meetings of State and National Medical Societies:

	Meets.	Next meeting.
American Association of Genito-urinary Surgeons.	May 28–31, 1895	Washington, D. C.
American Association of Obstetricians & Gynecologists.	Sept. 19–21	Toronto, Ont.
American Electro-therapeutic Association.	Sept. 25–27	New York City.
American Public Health Association.	Sept. 25–28	Montreal, Canada.
Association of Military Surgeons of the United States.	May, 1895	Buffalo, N. Y.
British Medical Association.	July 30–Aug. 2, 1895	London, England.
Canadian Medical Association.	September	St. John, N. B.
Idaho State Medical Society.	Sept. 10–12	Boise, Idaho.
Illinois State Medical Society.	May 21, 1895	Springfield, Ill.
International Medical Congress.	August, 1896	Moscow, Russia.
Medical Association of the State of Alabama.	April 16–19, 1895	Mobile, Ala.
Medical Society of the State of California.	April 16, 1895	San Francisco, Cal.
Medical Association of Georgia.	April 17, 1895	Savannah, Ga.
Medical Society of the State of New Jersey.	June 25, 26, 1895	Cape May, N. J.
Medical Society of the State of New York	Feb. 5, 1895	Albany, N. Y.

Tri-State Medical Society.	October 2, 3	Jacksonville, Ill.
Vermont State Medical Society.	October 11, 12	Montpelier, Vt.

Meetings of Philadelphia Medical Societies:

	Meets.	Next meeting.
Academy of Surgery,	1st Monday of month, Oct.—June.	Oct. 1
College of Physicians,	1st Wednesday of month, Sept.—June.	Oct. 3
Section of Ophthalmology,	3d Tuesday of month, Sept.—May.	Sept. 18
Section of Orthopedic Surgery,	3d Friday of month, Oct.—April.	Oct. 19
Section of Otology,	1st Tuesday of month, Oct.—May,	Oct. 2
Section of Surgery,	2d Friday of month, Oct.—May.	Oct. 12
County Medical Society,	2d and 4th Wednesdays of month, Sept.—June.	Sept. 12
Neurological Society,	4th Monday of month, Oct.—April.	Oct. 23
Obstetrical Society,	1st Thursday of month, Sept.—June.	Oct. 4
Pathological Society,	2d and 4th Thursdays of month, Sept.—June.	Sept. 13

The American Public Health Association will hold its twenty-second annual meeting at Montreal, Canada, September 25, 26, 27, 28.

The following topics have been selected for consideration:

"The Pollution of Water-Supplies." "The Disposal of Garbage and Refuse." "Animal Diseases and Animal Food." "The Nomenclature of Diseases and Forms of Statistics." "Protective Inoculations in Infectious Diseases." "National Health-Legislation." "The Cause and Prevention of Diphtheria." "Causes and Prevention of Infant-Mortality." "The Restriction and Prevention of Tuberculosis." "Car-Sanitation." "The Prevention of the Spread of Yellow Fever."

Papers are invited upon the following additional subjects:

"On the Education of the Young in the Principles of Hygiene." "Private Destruction of Household Garbage and Refuse." "Disinfection of Dwellings after Infectious Diseases." "Inspection of School Children with Reference to the Eyesight."

The Cholera in Europe.—It is reported that for the three days preceding September 3d there were 623 fresh cases of cholera and 313 deaths in Galicia, and in Bukowina 46 fresh cases and 25 deaths. One fresh case of cholera and 1 death were reported at Amsterdam on September 3d. In Maestricht there were 3 fresh cases and 1 death, and in Dordrecht 3 fresh cases and 2 deaths. The State Department has been notified by the Consul-General at Frankfort-on-the-Main that cholera has broken out at Burgela, near Marburg, Germany.

The Tri-State Medical Society (Illinois, Iowa, and Missouri) will meet in Jacksonville, Ill., October 2 and 3, 1894. Valuable papers are promised from leading members of the profession of Chicago, St. Louis, Kansas City, Indianapolis, Keokuk, Springfield, and other places. A large and profitable meeting is promised.

The West Virginia Journal of Medicine and Surgery is the name of a new monthly published at Huntingdon, W. Va., under the editorial control of Drs. C. C. Hogg, J. D. Myers, and J. Boyce Taylor.

Dr. William Cecil Dabney, Professor of Medicine in the University of Virginia, died August 20, 1894, at the age of forty-five years.

ORIGINAL ARTICLES.

NEPHRECTOMY, WITH REPORT OF A CASE.[1]

BY A. STEWART LOBINGIER, A.B., M.D.,
OF DENVER, COL.;
PROFESSOR OF PATHOLOGY AND CLINICAL SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO; SURGEON TO THE UNIVERSITY CLINIC; SURGEON ALTERNATE TO ST. LUKE'S HOSPITAL; PATHOLOGIST TO ST. JOSEPH'S HOSPITAL.

TOTAL extirpation of the kidney is an operation not frequently resorted to. Up to 1892 less than 350 cases had been reported. Since that date less than 50 additional ones have been recorded. About 15 of this number have been done in America.

The first nephrectomy, according to Smith's report, was performed in this country, at Milwaukee, in 1860. Walcott was the operator, and he supposed he was operating on an hepatic cyst. His patient lived fifteen days.

Simon, of Heidelberg, was the first surgeon to perform a systematic nephrectomy. This was in 1869, and since that date the operation has been undertaken by surgeons throughout the civilized world, with varying success. Twenty-five years of study and effort have not divested this operation of its formidable character; and the lowering of the mortality-reports has been largely the work of the last five years.

The indications demanding nephrectomy may be briefly summarized:

1. As a *dernier ressort* when nephrotomy fails.
2. When degeneration supervenes in a neglected movable kidney.
3. Intractable renal fistula after nephrotomy, or from any cause.
4. Tuberculous, suppurative, or cystic degeneration.
5. Destructive nephrolithiasis.
6. Traumatism causing rupture, hemorrhage, cloudy swelling, and acute suppurative degeneration.
7. Neoplasms.

Nephrotomy should often precede nephrectomy as a conservative measure. The patient is thus given an opportunity to rally and gain a resisting-power for the more formidable operation. Nephrotomy should be considered also in cases in which it is possible and practicable to save a sound portion of a partially degenerated kidney.

In cases of neglected movable kidney in which extensive degeneration, whether as hydronephrosis or pyonephrosis, has taken place, the kidney should be extirpated. In a very limited number of cases the condition may be relieved by nephrorrhaphy. But most of the cases met with are of such long standing that destruction has progressed beyond repair.

When a renal or urinary fistula has proved beyond possibility of closure, and the irritation from constantly dribbling and decomposing urine jeopardizes life, or makes it unbearable to the patient from an esthetic standpoint, nephrectomy offers an effectual and reasonably safe remedy. The extirpation of the kidney under such circumstances should be undertaken only after every other possible effort and operative device has been resorted to to close the sinus.

Tuberculous degeneration of the renal substance is a positive indication for total extirpation. Whether this degenerative change has been extensive or limited does not signify. The only point to determine in such an issue is whether the constitutional resistance of a patient, often already greatly reduced in physical tone, will prove sufficient to endure the shock of the operation.

Recent statistics of tuberculous kidney show nephrectomy to have been fatal in only about 36 per cent. of the cases. This is a somewhat lower death-rate than applies to simple pyonephrosis, of which the mortality ranges from 35 to 40 per cent.

If suppurative change has existed for a period of a year and a half or two years, the chances are strong that the entire renal parenchyma is destroyed. This destruction will be hastened when the exciting cause is a small calculus in the pelvis, just large enough to act as a valve over the ureter, causing backward pressure of pent-up urine, or when it is the excitant of constant traumatism of the neighboring calyces.

Stone in the kidney is not in itself a sufficient indication for total extirpation. If the calculus be small, whether single or multiple, there will always be imminent the danger of engagement in the ureteral expansion, and occlusion of the duct. Yet the hope of resolution by means of proper solvents mitigates the formidable features of such a case. This hope has no foundation in a case of larger calculus

[1] Read before the Colorado State Medical Society at Denver, June 20, 1894.

when the stone lies in or near the calyx, or loosely in the pelvis. Sooner or later the irritation and obstruction will cause cloudy swelling, inflammation, and suppuration, with degeneration of the pyramids, thinning of the cortex, and progressive destruction of the parenchyma. The longer a stone of such character is allowed to remain without surgical interference, the more remote grow the possibilities of relief by nephrotomy and the more certain the necessity of nephrectomy.

Instances of traumatism causing rupture, extravasation, or acute suppurative change, while not of common occurrence, have been met with sufficiently often to merit a place in the category of indications for nephrectomy. The virulence of the pyogenic bacteria in acute septic cases upon tissues illy immune to their toxic products renders nephrectomy more formidable than in the chronically septic cases.

Primary new-growths common to the kidney, which call for total extirpation, are usually sarcoma and carcinoma. Sarcoma is found the more frequently. Rhabdomyoma and adenoma are less commonly found. In malignant involvement here, as in other tissues, the merit of operative interference is measured by the extent of infiltration. The diagnosis and the extirpation must be made early, or the hazard is without avail.

The high mortality of nephrectomy has long been well recognized, and has for years placed the operation in the category of the most formidable of operative procedures. Statistics have been collected with great care by the best of men, but up to a half-decade ago the mortality, as given by Billroth, Gross, Harris, Weir, and Baum, ranged from 44.6 to 50 per cent. Later tabulations have shown a considerable decrease in the mortality. At present it may be said that the mortality of total extirpation will, in the hands of different operators, range from 36 to 40 per cent. Variations from this percentage will arise from difference in disease, in resisting-power of the patient, and surgical technique.

Nephrectomy is usually a long-delayed operation, undertaken only after every other measure has been tried. The task of one kidney doing the work of two has usually been assumed by Nature some time before the operation of extirpation has been determined upon. The danger in too long delay in these cases is one that should always be borne in mind. Statistics will make a great gain on the favorable side when this fact is thoroughly appreciated and acted upon.

The *diagnosis* of a condition demanding nephrectomy is frequently of less difficulty than the determination of the integrity of the other kidney. The exploratory incision, while easy of resort, is not always expedient. This is so well appreciated that a multiplicity of devices for compression, exploration, or catheterization of the ureter have been devised. Some of these have merit, and, in the hands of patient and dextrous operators, prove reliable. Most of the devices invented, however, are obsolete. Polk's clamp, or the ureteral catheter with illumination of the bladder, has more nearly approached the ideal aid to diagnosis. The exploratory incision always remains as an honorable and justifiable procedure in desperate cases, when all else has failed.

If tuberculosis be suspected, examination of the pus or caseous particles for the tubercle-bacillus will prove an important aid to the differentiation between simple and tuberculous pyonephrosis. Portions of the deposit should be taken up with a pipet and spread between the planes of two small slabs of plate glass, in order to discover the caseous material; for it is in this that the bacilli are found in greatest numbers. Very rarely is the bacillus found free in the urine, even in the most unmistakable and advanced cases of genito-urinary tuberculosis. When the caseous material is found, it may be spread, stained and mounted in the usual way.

The determination of the presence of a calculus is more difficult. If its weight be from fifteen to forty grains, less pain will be caused than when the concretion is smaller. The increase and decrease in the amount of sediment in the urine at irregular intervals points to stone. It will be observed that at the same time there will occur, conversely, an increase and decrease in the size of the tumor and tenderness on pressure. The explanation of these phenomena is too palpable to call for more than mere mention.

In case of calculous pyonephrosis, the presence of blood in the purulent sediment will be more common than in case of tuberculous destruction. In the latter condition the blood appears earlier in the disease, and is not the periodic concomitant observed in the exacerbations of the calculous variety. In this the hemorrhage is largely the result of traumatism and irritation of the pelvis and pyramids by the loose calculus.

Pain is a symptom of little value differentially. Three or four conditions of the kidney may produce pain of essentially similar character and degree.

The general constitutional dyscrasia of the patient, whether tuberculous or rheumatic, may lend aid to the other and more exact methods of differentiation.

I have purposely omitted comparative estimations of urea, as these are of no value from a differential standpoint.

As to the *operation* of lumbar nephrectomy, the details carried out in the case described later will suffice for this paper.

When, from the character or location of the

tumor it becomes necessary to perform abdominal nephrectomy, the operation need depart very little from the technique of the removal of any other tumor from the abdominal cavity, unless the operator prefers the more modern incision of Langenbuch through the linea semilunaris.

Some care will need to be exercised in passing through the peritoneal covering of the tumor, making the opening through the mesocolon externally between the colon and the parietes; for division and ligation of the vessels in the inner layer may be followed by intestinal gangrene. The treatment of the vessels and ureteral stumps is essentially similar to that adopted in lumbar nephrectomy, namely, to drop them into the wound if healthy. If the ureter be suppurative, caseous, or calcareous, it is best treated by stitching its extremity into the lips of a counter-incision made above the crest of the ilium, after the method described by Morris.

Report of a Case. On March 1, 1894, the patient whose case is here reported consulted me at my office concerning a vesical and renal difficulty of three or four years' standing, which was attended with pain on micturition and a large deposit in the urine. She also complained of pain along the right ureteral tract and in the lumbar, right umbilical, and lower hypochondriac regions. She was furnished a sterilized bottle, which was returned on March 2d containing the urine for the preceding twenty-four hours.

The precipitate from 200 cc. in a two-inch cylinder was seven-eighths of an inch in depth. Following is the analysis.

Physical and chemic characteristics:

Quantity for twenty-four hours, 1150 cc. Color (supernatant), reddish-brown. Odor, fetid. Reaction, slightly acid. Sp. gr., 1028. Deposit, quantity and general appearance—large quantity, pinkish-yellow, sanguino-purulent. Urates, none. Phosphates, none.

Albumin, 33 per cent. per volume. Sugar, none.

Microscopic examination:

Bacteria: Staphylococcus pyogenes (abundant).
Streptococcus pyogenes (abundant).
Micrococcus ureæ (scant).

Pus, abundant, deposit largely pus. Casts, none. Blood, considerable amount. Epithelium, abundant. Crystals, none.

I examined the pus and flocculent particles for the bacillus tuberculosis, with negative results.

An appointment was made with the patient for a physical examination on March 4th. At 4 P.M. on that date the following history and conditions were elicited:

Mrs. J. H. A.; was thirty-two years old, married six and a half years, and gave a good family history. There were no cases of renal or calculous disease in any branch of the family. The woman had borne four children; the first five years before, the youngest was ten months old. The patient had a miscarriage in the sixth week of gestation, two and a half years before. Eight months later, while in the mountains, she had an attack of acute lobar

pneumonia, involving the lower lobe of the left lung. This confined her to bed eleven days, and her convalescence was tedious and protracted. She had had a slight cough from this time, mostly at night, which had been accentuated since the birth of her last child, and she now coughed during the day as well. She had never had a cough before the attack of pneumonia. She first noticed the deposit in her urine four years ago. It was not constant, nor was there a competent analysis made to determine its character. There would be periods when this deposit would abate and apparently disappear; but it would recur from time to time, and for a year and a half had maintained a constant and somewhat increasing quantity.

She now suffered from pain in the upper right lumbar region, extending into the right umbilical region, along the right ureter and at the neck of the bladder; experienced great lassitude and had lost ambition and spirit. Her appetite was only fair, and at times she had chilly sensations, which pointed to sepsis. She nursed her ten-months-old baby and endeavored to look after the duties of her household. She said that she was growing weaker day by day. She had the appearance of a tuberculous subject, with a pale, poorly nourished, darkly veined, transparent integument, prominent eyes, pinched and anxious physiognomy and frail movement. Her weight three years ago, and before the miscarriage and pneumonia, was 150 pounds; she now weighed 108 pounds, and her temperature, at 4 P.M. was 99.1°; her pulse 76; her respiration 22.

Examination of the lungs revealed pleuritic adhesions at the base and throughout the lower lobe of the left lung, with some dulness posteriorly. The fremitus was increased at the apex of the right lung and at the outer angle of the apex of the left lung. No râles or distinguishable areas of consolidation were detected elsewhere. The respiratory action was feeble; the expansion symmetrical, but limited. The stomach, spleen, and liver were apparently normal. At the junction of the right hypochondriac with the right umbilical region, between the linea alba and the right axillary line, was a firm tumor about four inches in diameter, that was so tender on pressure that the patient bore manipulation with difficulty. In the dorsal decubitus the tumor slipped away into the lumbar-hypochondriac region. Its prominence, however, was only apparent ventrally. Dorsally the quadratus prevented gravitation and protrusion of the mass.

In the erect posture the tumor became markedly prominent and gravitated downward and inward, so that its lower pole was three-fourths of an inch below the umbilical line. On bimanual manipulation it was evident that the tumor-mass was not as mobile as would appear from a cursory view, the contraction and relaxation of the abdominal wall and movement of the neighboring viscera causing the deception. Following downward, and making firm pressure along the right ureteral tract, elicited great tenderness all along the duct. This tenderness was not localized, but evenly distributed. Examination of the left renal and ureteral region in a similar manner revealed no tenderness, tumor, displacement, or other abnormality.

Examination *per vaginam* and bimanually showed the uterus to be small, high up, with neither version, flexion, nor laceration. The urethra and the neck and *bas fond* of the bladder were tender on pressure; the right ovary low and sensitive, and the tube somewhat thickened. The left ovary and tube were normal. Examination *per rectum* and bimanually showed the right ureter, from its emergence in the bladder to the brim of the pelvis, excessively tender. This tenderness was almost as marked as over the tumor itself. On the left side the firmest pressure and manipulation revealed no tenderness or discomfort.

Diagnosis. Right pyonephrosis, either calculous or tuberculous, with an intercurrent cystitis; the medullary portion of the kidney probably destroyed, and the organ adherent to contiguous structures.

An operation, either nephrotomy as a palliative or nephrectomy as a radical measure, was advised without delay. The patient was made aware of the mortality attending nephrectomy, and on the other hand the jeopardy to life if not relieved of her septic condition. She asked for a few days to determine what she should do. Meantime she was ordered to wean her baby at once; tonics were prescribed, and the question of operation was debated freely with her friends. Seven valuable weeks were consumed in this desultory discussion, and finally, at my request, a consultation, which I had already suggested six weeks before, was arranged with Dr. W. B. Craig.

On April 25 Dr. Craig made an examination, confirming the points and diagnosis herein set forth, and advised an immediate operation.

On April 27, at St. Luke's Hospital, the operation of lumbar nephrectomy was performed by Dr. Craig and myself, Drs. Axtell and Bagot assisting. The patient had been prepared as for abdominal section. After sterilizing the lumbar area, a firm pad was placed under the left flank. Starting half an inch below the last floating rib and two inches external to the spine, a diagonal curvilinear incision four inches in length, was made downward and forward over the crest of the ilium. Passing inward, the external border of the quadratus was used as a guide, forming the posterior boundary of the incision; the fatty capsule was taken up and incised, and the kidney brought, by upward pressure on the abdominal wall, quickly into the field.

Dorsally and laterally the kidney was free from serious adhesion, but about the pelvis and vessels and at each pole it was firmly and extensively adherent. Considerable time was occupied in dissecting away the organ, using the fingers where practicable, and the scissors where there was firm connective-tissue union. The latter condition was especially marked at the upper pole, where a solid mass of fibrous tissue, an inch long and three-fourths of an inch in diameter, had formed, including in it the supra-renal capsule. At the lower pole the kidney was larger, softer, and, as would be expected, showed evidence of recent and continuous inflammatory

change from the presence of the pus which gravitated to that area.

It was planned to dissect out the kidney and enucleate it, if possible, without opening into the cavity of the abscess, and by this means guard against infecting the wound. But the adhesions of the lower pole were so extensive, and the parenchyma of the kidney composing the abscess-wall so degenerated, that, in a final effort to free the small remaining adhesion the wall was ruptured and the wound infected. The parts were at once copiously irrigated, the kidney freed from remaining adhesions and enucleated, the ureter and vessels being ligated separately with strong silk. The ureter was stitched in the lower angle of the wound, and a small soft rubber drain inserted into the duct for four inches. The vessel-stump was dropped into the cavity, and the latter packed with iodoform-gauze. Three or four sutures were introduced in each angle of the wound and the center left open for drainage.

The operation, from the first incision to the completion of the sterilized dressing, occupied one hour and five minutes, the freeing of the adhesions consuming most of the time.

The patient's pulse, respiration, and general condition were excellent at the end of the operation. She was left quietly resting on the table in the operating-room for twenty minutes after completion of the dressing and withdrawal of the anesthetic, during which time the temperature of the room was being reduced from 85° F. to 70° F. She was then removed to a room and placed in bed, surrounded with warm bottles, and the usual *régime* observed in cases of abdominal section carried out. She vomited but once in the first forty-eight hours, and but twice afterward. Her temperature and pulse-rate were highest on the second day, 102.2° and 125 respectively. On the fourth day she was normal, and remained so.

It was well understood before the operation that we should likely encounter pus, and that it would be heavily charged with both streptococci and staphylococci, as appeared from examination of the pus in the urine. It was morally certain, therefore, that an elevation of temperature additional to the operative curve would result from the infection caused by rupture of the abscess-wall. Had the patient not been somewhat immune from her long-standing septic condition, a much higher temperature-curve would doubtless have resulted.

The tube in the ureter was removed on the sixth day. The ureter had been syringed once a day with hydrogen dioxid and boric-acid solution. The bladder had been irrigated twice daily with a solution of boric acid, borax and sodium chlorid. The deposit in the urine had almost entirely subsided the day after the operation, but it was thought better to restore the tone of the bladder by removing the very slight amount of pus being formed there; hence the irrigation.

The sutures retaining the ureter, and those in the wound were gradually removed from the tenth day. Four weeks after the operation the patient was discharged in good health. She had greatly gained in color, strength, and weight, and has continued to improve every day since.

The kidney removed measured five inches in length, two and a half inches in width, and one and a half inches in thickness, being one inch and a half inch larger respectively in its two major dimensions than the normal kidney of a woman. The weight of the organ was 175 grams (6 ⅛ oz.).

On section it was found to be studded with abscess-cavities throughout the medullary portion and involving much of the cortex. The pelvis was greatly distended and contained a calcium-oxalate calculus weighing 1.25 grams (20 grains).

The calculus had caused destruction by traumatism and occlusion of the ureter, producing backward pressure. There was no evidence of tuberculosis. On making a microtome-section, and staining for the tubercle bacillus in the tissue, I found none. Other sections of healthy-looking portions of the cortex were made and stained with logwood. The appearance of the tissues was most characteristic, showing the parenchyma to be entirely destroyed by granulo-fatty, cirrhotic, and amyloid degeneration.

THE ENCOURAGEMENT AND SUPPORT OF THE LABORATORY-TEACHER AND LABORATORY-SPECIALIST.

By A. P. OHLMACHER, M.D.,
of Cleveland, Ohio;
Professor of Pathology and Bacteriology, Medical Department University of Wooster; formerly Professor of Embryology, College of Physicians and Surgeons, Chicago, and Professor of Pathology, Chicago Polyclinic.

The evolution of medical education has created the laboratory-teacher as a recent and very essential addition to the medical faculty. The profession has scarcely yet learned the importance of the work assigned to the laboratory-instructor; nor has it learned how to provide for the maintenance of its new creature.

So long as the commercial spirit pervades medicine, so long will teachers of medicine teach for selfish ends. It is not reasonable to expect an unsalaried teacher to devote his time and energies to his students without looking to his self-interests. As a consequence, the teaching of medicine has not been, as a general rule, broadly and fearlessly honest. Students have not been taught to become self-reliant practitioners in the college-courses. These remarks apply, of course, especially to clinical teachers.[1]

In the good old days of medical education, when staphylococci and streptococci and diplococci and karyokinetic figures did not disturb the minds of educators and students of medicine, laboratory-

[1] I desire to accredit the foregoing ideas to Dr. Bayard Holmes, who has from time to time expressed them in a somewhat different form, and in different relations. The scheme for the development of a laboratory-specialism upon the lines suggested is, however, original, if not novel.

courses and laboratory-teachers were easily maintained. The chemic laboratory and the professor of chemistry offered the only problems to the faculty. Here, as a general rule, everything was easily settled, for his colleagues could recommend to the professor of chemistry well-paying mineral-water and baking-powder agents, from whom the chemist usually managed to obtain sufficient compensation without trespassing on the college-treasury. Failing in this, the professor of chemistry was appointed adjunct to the chair of diseases of the rectum, and, content to await his time, he taught chemistry until the chair of rectal diseases became vacant. Anatomy has always been looked upon as the handmaid of surgery, and for this reason the laboratory-anatomist has rarely given his colleagues concern.

When it became fashionable to give the so-called "laboratory-courses" in histology and in pathology, the instructor was still content to serve this preliminary apprenticeship in order to see his name on the faculty-list of the college-announcement, and with the promise of a slice of clinical toast later in his service. When laboratory-courses in histology and pathology consisted in passing from student to student beautifully colored sections of tissue prepared by the demonstrator, or, more often still, imported from Germany, which were magnified by the exhibition-microscope; or when, later still, these courses consisted in passing dishes of stained sections in clove-oil, all labelled and ready to mount, then a laboratory-teacher could afford to serve his apprenticeship while he waited impatiently for a clinical promotion. Of course the student learned little to make him independent in these days of laboratory-teaching, but he had never learned to look for anything more in other branches of medical instruction.

Gradually, however, the demands for a thorough and liberal instruction have made themselves felt, and as an outcome we witness an ever-increasing agitation for improved medical education. Especially is this true of laboratory-instruction, and a demand for better laboratory-teaching and for laboratory-teachers has arisen. It has come to be recognized among thoughtful medical educators that laboratory-instruction and laboratory-instructors must be entirely divorced from a clinical or a commercial relation. The instructor who makes his laboratory-work the stepping-stone to a clinical specialty can at best do only half-hearted work. The laboratory-instructor who, like his ancient predecessor, the chemist, makes laboratory-work a commercial enterprise, cannot be honest to himself or to his students.

Recognizing the fact that laboratory-teaching calls for much skill, much patience, and much hard work, and that a medical man who is familiar with the remuneration and independence of the practice of medicine must expect, at least, a commensurate compensation for his work, the problem arises, how to provide for the laboratory-teacher. Pay him a salary? Very well. What salary will afford him an equivalent of what his skilful brother-physician earns in his practice? How many of the medical schools of the United States can afford to pay their laboratory-teachers salaries of five thousand, ten thousand, or even twenty thousand dollars a year? And still these sums of money are earned by skilful practitioners; and if the laboratory-teacher be compelled to lay aside all clinical claims, as he surely must to do good laboratory-teaching, is he not entitled to at least a proportional compensation?

In the absence of large endowments—endowments large enough to permit the salarying of all medical instructors—some provision must be made for the teachers of the "unpractical" subjects of the medical curriculum.

As the outcome of certain personal experiences, and as a result of much thought upon this subject, I am prepared to offer certain suggestions for the temporary support of laboratory-teachers in medicine—that is, for the support of those teachers until medicine shall become an endowed institution or a State institution.

In the first place, the laboratory-teachers in medical schools should be encouraged to elect laboratory-teaching as a life-work. They should be discouraged from entering into the clinical fields more than their work demands; and they should not engage in routine private practice. All laboratory-teachers should be paid a salary, and this salary should be as large as the college can afford, though doubtless only a fraction of what a thoroughly good and enthusiastic teacher would earn. Finally, the colleagues of laboratory-instructors should provide for them collateral support of a nature to be discussed later on.

There should be a graded series of promotions in the corps of laboratory-teachers similar to that which obtains to-day among clinical teachers. Certain laboratory-branches, as biology, first-year chemistry, histology, and embryology, for instance, should constitute the introductory work for an aspiring laboratory-man. These branches can be assigned to young men of recognized ability who are recent graduates in medicine. These men should be paid a salary sufficient to enable them to live without practising medicine. The experience obtained in this work would be an invaluable introduction to the higher, and, if they may be so called, more "practical" laboratory-branches, as pathology and bacteriology, physiologic chemistry, and laboratory-medicine.

It is especially to the support of the "practical" laboratory-teachers that attention will be here di-

rected. These teachers must also receive a definite salary. In the present poverty of medicine, however, this salary cannot be a sufficient compensation for the time and work spent in preparatory teaching, nor can it compensate for the valuable services of a man who gives his life to laboratory-work. The laboratory-teacher of pathology, bacteriology, chemic physiology and pathology, and of laboratory-medicine must then receive further compensation. How shall this compensation be provided?

It has already been suggested that his colleagues should give the laboratory-teacher collateral support —that is, they should lend him all possible assistance in obtaining work relating to his laboratory-service, and they should assist him in obtaining pay for this work.

The past few years of medical progress have brought into special prominence the value of laboratory-methods in all lines of clinical medicine and surgery. The vast majority of American clinicians are to-day untrained in laboratory-methods, or, being trained, are too much occupied to apply these methods in their clinical work. These clinicians are coming more and more to look to the laboratory for assistance in diagnosis and treatment, and the time now seems ripe for a new specialist in medicine—*the laboratory-specialist.*

Recognizing that laboratory-methods find more and more application in clinical medicine and surgery, and that clinicians cannot apply these methods, it remains, of course, to place work of this character in the hands of the laboratory-specialist.

The laboratory-teacher's services have already been demanded by his clinical colleagues. It is further true that while these services have been demanded and freely given, they have not been fairly recognized nor fairly compensated. Every laboratory-worker has on his table bottles of urine, bottles of sputum, and bottles of tissue, that represent hours of patient work; but few laboratory-workers have bank-accounts composed of earnings derived from this work. His clinical colleagues have largely treated the laboratory-teacher as a servant. Indeed, there can be no doubt that the tendency of many clinical men, and especially surgeons, has been to look upon a laboratory-colleague as a very convenient assistant, who ought to feel well paid for his laborious examinations for the privilege of obtaining certain valuable specimens or of witnessing the surgeon's skilful operations.

That this kind of treatment is unjust every fair-minded physician must admit. The knowledge and skill required in the prosecution of the many delicate laboratory-manipulations place the laboratory-specialist at least on a par with the most skilful clinicians in medicine and surgery. This being true, and the necessity of laboratory-assistance being recognized, why cannot the laboratory-specialist be treated with the same professional courtesy as the clinical specialist?

The laboratory-specialist can and should receive the same treatment at the hands of his professional brethren as the clinical specialist. He should be treated as a skilful consultant; not as an assistant. His services should be obtained under the same ethics as govern other professional consultations. When the physician or surgeon has a case calling for a laboratory-diagnosis, the laboratory-specialist should be called into consultation, and he should receive for his services a consultation-fee commensurate with the character of the work and the means of the patient.

The field of the consulting laboratory-specialist is very wide at present, and is increasing each day. The methods of the laboratory are each day being extended farther and farther into clinical medicine and surgery. A few examples will serve to indicate the field of the laboratory-consultant, and to suggest the proper course of procedure to the clinicians.

Professor A, a surgeon of much skill, and with a large and remunerative practice, has a case something like this: A man, in good circumstances, has been referred for the treatment of an axillary adenitis, secondary to an infected wound of a finger received some two months previously. The glands have enlarged slowly during the last month, and are only slightly painful on pressure. The important question of a correct diagnosis at once enters into consideration. Is this adenitis the result of a purely pyogenic infection, a mixed infection, or a purely tuberculous infection? Professor A sees at once that, in order to make the diagnosis upon which so much depends, he must call for assistance upon Professor B, the pathologist. Professor B comes to the operation with his tubes of blood-serum, agar, and gelatin, and with a guinea-pig for inoculation. He obtains the freshly removed glands, and with great care makes inoculations upon his agar, gelatin, and blood-serum; and he inoculates the guinea-pig with a bit of one of the glands. Upon his arrival at the laboratory the pathologist proceeds to make a large number of smear-preparations from the suspected glands, which he stains for the tubercle-bacillus, without finding that organism; he also hardens pieces of the glands, and during the next two or three days he cuts many sections of the gland-tissue, which he also stains for bacteria. All of this work furnishes negative evidence, and, further, at the end of two or three days, it is seen that the culture-tubes inoculated at the operation remain sterile. This practically excludes active pyogenic infection from the diagnosis. Now comes the tedious wait of three weeks, until

the inoculated animal is seen to be emaciating and about to die. The animal is killed, and upon post-mortem examination is found to be tuberculous. The pathologist reports his diagnosis to the surgeon, who has waited rather impatiently for it. Professor A thanks Professor B, and proceeds to further operation upon his patient. Professor B sighs for the day when he too can become a great clinical surgeon. He believes that, in this particular case, he has done more work, more important work (to the patient), and more skilful work, than Professor A, and he believes that in all justice he should receive a fee for this work equivalent to that of his surgical colleague. But the services of laboratory-specialists are not recognized at this time, and Professor B is compelled to do what hundreds of fellow-laboratory-workers are doing all over this country—to give his time and services without just compensation.

In this hypothetic case we would suggest that Professor A might have treated Professor B in this manner: Professor A should have informed his patient that in order to obtain a correct diagnosis he must call into consultation Professor B, a skilful laboratory-specialist. He should have informed his patient that he much preferred the consultation with Professor B to that of another surgeon who, like himself, could only add surmise to uncertainty. Of course, the patient would agree to anything that Professor A advised for his good; and, instead of coming into the case as an obscure assistant, Professor B would come introduced to the patient as a skilful consultant. When his work was ended, Professor B would render a bill for his services to Professor A, who would collect the fee from the patient.

A patient from an outlying town is recommended to Professor A, the surgeon, for the treatment of a multiple synovitis affecting both knee-joints and one elbow. Professor A is in serious doubt as to the nature of the disease. Is the infection pyogenic, gonorrheal, tuberculous, or mixed? Professor A cannot make a diagnosis without the assistance of a laboratory-expert, and he feels that conscientiously he cannot treat his patient without making a correct diagnosis. Consequently he again calls upon Professor B, who arrives at the hospital with his syringe, test-tubes, and culture-media, and obtains some of the fluid from the joint for examination. After a series of carefully conducted experiments, including again the inoculation of a guinea-pig, Professor B reports that the fluid contains neither active pus-cocci nor tubercle-bacilli, and that in all probability the infection is gonorrheal. Here again Professor A might have called Professor B in consultation, introduced him to the patient as a consultant, and permitted him to receive a fee for his services. Had it been necessary to call Professor C, the physical diagnostician to decide upon the question of the integrity of the patient's lungs, Professor A would have adopted the latter course. Still it certainly is an open question whether Professor C, with his stethoscope, would have done as much work, or as skilful and patient work, as was required of Professor B.

Examples like the foregoing, in which the surgeon requires the assistance of a laboratory-consultant, might be given in considerable numbers. The bacteriologic analysis of exudates in the chest, in the abdomen, and in the joints, is assuming a very important place in surgical diagnosis. The examination of urine for pyogenic products is rapidly becoming an important factor in the diagnosis of concealed purulent accumulations. The microscopic examination of tumors has always been recognized as an essential part of surgical diagnosis.

These are some of the examples, then, of the cases in which the surgeon is compelled to look to some laboratory-worker for aid. Is it not time that the work of a colleague which means so much to the surgeon's success should be properly dealt with? Is it unreasonable to ask that the laboratory-expert be treated with the same professional courtesy as any other skilful specialist? We believe that every fair-minded surgeon will, once his attention has been properly directed to this matter, treat his laboratory-colleague with proper regard for the character and value of his services. The difficult and important work of this new specialist should not be hidden from the public gaze, while the clinicians win glory and admiration for their brilliant work. The laboratory-consultant should not, in those cases in which he renders valuable services to other practitioners and to the public, be compelled to secretly prosecute his work in the confines of his dingy laboratory, while the clinicians reap credit and reward for the work that could not have been accomplished without the aid of the laboratory-expert.

What has been said of the relation of the surgeon to the laboratory-specialist may also be applied to the other clinical specialists—to the specialist in internal medicine, to the gynecologist—and to the general practitioner. All of these physicians look more or less to the laboratory for assistance in diagnosis. In internal medicine, for instance, there is the examination of urine, blood, and sputum, for a large variety of pathologic conditions. Here, too, we have the very important culture-method for the diagnosis of diphtheria, a method that should be applied in every case of suspicious sore-throat, and one that must prove of incalculable benefit in diagnosis, treatment, and prophylaxis. How few clinicians have the facilities at hand, or the knowledge of bacteriologic manipulation necessary to apply the culture-test for diphtheria? In case the clinician is compelled to call upon a laboratory-expert for this piece of work, should he not, instead of obscurely

sending a swab to the laboratory, invite his colleague into consultation, enable him to procure his own specimen with those precautions that he best knows are essential; and, finally, when a positive diagnosis is reached, should not the laboratory-expert be allowed to collect a fee from the patient for his services?

Similarly, when the gynecologist desires an examination of a piece of tumor-tissue, or of a piece of uterine mucosa, he can call the laboratory-specialist in consultation with him to the patient's bedside, where the tissue can be observed *in situ*, and then be preserved with proper precautions—all matters of great importance to a laboratory-diagnosis, while at the same time affording opportunity for the proper professional treatment of the laboratory-associate.

It is not contended that all possible laboratory-examinations should be made in consultation as indicated in the foregoing examples. A certain kind of routine work, like the ordinary examination of urine, and of sputum, could constitute the "office-work" of the laboratory-specialist. The specimens could be sent to the laboratory, and upon a laboratory-report an ordinary fee could be charged for the examination, without the formality of consultation. But all cases demanding a more careful examination, as bacteriologic analyses, blood-examinations, and tissue-examinations, should be treated as consultation-work.

It is quite impossible to indicate all of the cases in which the clinical specialist and the laboratory-specialist could coöperate to their mutual advantage and to the advantage of the patient; but enough has been said, it is hoped, to illustrate the principle involved and to indicate the only fair course of procedure. If the clinical specialists in the large medical centers of this country will treat their laboratory-colleagues as here suggested, and will make due efforts to bring all legitimate work into the hands of the laboratory-workers, the vexed question of the support of the laboratory-instructors in our colleges will be temporarily settled. Then laboratory-experts will not be driven to form corporations for mutual protection, as has already unfortunately been done. By thus rewarding justly the skill of the laboratory-expert, many young men of promise could be encouraged to enter upon laboratory-work as a specialty, assuring an adequate supply of laboratory-teachers, and opening the way for original researches in laboratory-medicine. The enthusiastic laboratory-student would cultivate his chosen specialty for its own sake, and not prosecute it temporarily as a stepping-stone to a clinical specialty. The laboratory-teacher could then well afford to do the large amount of purely scientific work that naturally comes from an unpaid hospital-service; just as the clinician can afford to do this work when he is assured of an indirect compensation.[1]

ON EPILEPSY IN EARLY LIFE, WITH ESPECIAL REFERENCE TO THE COLONY-SYSTEM IN THE CARE AND TREATMENT OF EPILEPTICS.

By WILLIAM PHILIP SPRATLING, M.D.,
of New York City;
formerly First Assistant Physician New Jersey State Hospital, Morris Plains; Member of New York County Medical Society; Member of Harlem Medical Association of the City of New York, etc.

The very fact that epilepsy has successfully resisted for so long a time the efforts of science to solve the cause of its origin renders the affection always of interest. It is unfortunate, however, that, in a measure at least, its very frequency has a tendency to cause many to regard it as a commonplace affection—a malady that can rarely be cured, and therefore one that has to be endured. This fact, so far as it is applicable, is to be deplored.

Epilepsy is a widespread disease. It is estimated, on a conservative basis, that two persons in every thousand of the population of this country suffer from it in some one of its forms. If all cases of epilepsy could be put on record I have no doubt but that this estimate would be materially increased. Epileptics in the better walks of life and their friends and families are prone to conceal the fact of the existence of the disease.

Reckoning on the basis that two persons in every thousand are epileptics, there would be about nineteen hundred in New York City alone, about twelve thousand in the State of New York, and about one hundred and twenty thousand in the United States.

Epilepsy has been known to exist for some thousands of years, and from time immemorial its victims have been made the receptacles into which drugs, compounds, and decoctions have been literally poured without stint or cessation.

Master-minds have studied the disease in all ages. Hundreds of years ago Hippocrates described epilepsy so accurately that modern clinicians find but little to add to his masterly description. With medicinal, dietetic, hygienic, and surgical treatment we have done our best; and yet, what have we accomplished? It is not a pleasant thing for enlightened science of the nineteenth century to contemplate, but it is a fact beyond controversy

[1] While this article was being prepared for the press I encountered the appeal of Dr. John Slade Ely ("The New Relations of Pathology and Practical Medicine as Bearing upon the Pathological Departments of our Hospitals," Medical Record, August 25, 1894), who makes a very reasonable petition for the salarying of all hospital-pathologists. Greatly as it is to be desired, we fear this suggestion will find tardy acceptance in the present poverty of medicine; and the hospital-pathologist, like the hospital-clinician, will be compelled to look to his associates and to the public for his support.

that, with all our resources, we do not to-day cure 1 per cent. of the cases of idiopathic epilepsy that come under our care. I purposely omit, of course, including in this estimate reflex, traumatic, and such other varieties of epilepsy as have a definitely ascertainable cause, and for that reason are frequently amenable to treatment.

One of the most interesting facts in regard to epilepsy is that it is peculiarly, indeed, I may almost say essentially, a disease of early life. True, it sometimes begins late in adult life. Cases are on record in which the first convulsion occurred after the age of sixty. But when the seizures arise *de novo* at such a late period they are usually of traumatic and not of idiopathic origin. When simple idiopathic epilepsy develops in an idividual who has reached adult life it will usually be found that convulsions had occurred during infancy or childhood.

Seventy-five per cent. of all cases of epilepsy begin under twenty years of age, and nearly 50 per cent. between ten and twenty, the maximum being at the ages of fourteen, fifteen, and sixteen. Again, twelve cases among every hundred begin, according to Gowers, during the first three years. This is a serious fact and one worthy of being remembered when we see an infant or young child suffering for the first time from convulsions, *no matter what the cause may be.*

Females suffer more frequently from epilepsy than males, the proportion being about six to five.

An etiologic factor of vital importance in the study of epilepsy, as well as of other diseases of the nervous system, is heredity. No single cause plays a more conspicuous part. The best observers, including Gowers, trace an inherited tendency to epilepsy in 35 per cent. of all cases. Epileptic children, however, do not come from epileptic parents in all instances. Sixty-six per cent. of those who inherit an epileptic tendency have epileptic parents. The remaining 33 per cent. are born of parents who are or have been insane, or who suffer from chronic alcoholism.

The heredity taint is transmitted to females more frequently than to males. An inherited tendency is found in 33 per cent. of male epileptics, and in 37 per cent. of female epileptics.

During the first ten years of life the number of females that develop epilepsy exceeds the number of males by 6 per cent. This is explained on the ground that when the hereditary predisposition is maternal more females suffer than when the predisposition is transmitted through the father. If this be true, and we have the testimony of the best observers that it is, it affords an excellent illustration of the doctrine of the "survival of the fittest." It would seem that the females, at some time and in some manner not explained, acquire a greater degree of susceptibility to the disease than is acquired by the opposite sex, and that the natural and physiologic propagation of this susceptibility consists in handing it down to the like sex from generation to generation.

Inherited epilepsy usually develops before the age of twenty. It may not, however, appear until late in life. A singular fact in this connection is that when idiopathic epilepsy appears in the parent at a certain age—say twenty-eight, for instance—the offspring is far more liable to develop the same disease at about the same age. This patho-physiologic fact holds true in reference to other diseases, notably pulmonary tuberculosis and certain forms of insanity.

Next to heredity it is my firm conviction that dentition, when severe, and *when acting on an organism that bears the impress of transmitted weaknesses,* plays the most important rôle in causing epilepsy in early life. Indeed, I fully believe that the importance of teething in this respect has not been accorded the careful attention it deserves.

In speaking of epilepsy in infancy, Gowers uses these words: "Of all the cases that commence in infancy at least three-quarters date from infantile convulsions ascribed to teething." This author also believes that rickets acts as a combining cause in such cases.

The relationship between dentition and epilepsy is of peculiar interest, from the fact that it too often happens that just at this period the seeds of future insanity are sown. Infantile insanity is extremely rare, but the undermining of the mental powers that may not be apparent until some exciting cause later in life causes it to develop often begins at this critical period.

Through correspondence I recently secured the views of several well-known physicians bearing upon the relationship between dentition, epilepsy, and insanity. Some of them I give here:

Dr. Abram Jacobi says:

"Every convulsion, ever so slight or short, may produce cerebral hemorrhage, with all the possible results —epilepsy, idiocy, paralysis, and insanity. Such cases are, unfortunately, frequent."

Dr. G. Alder Blumer, Superintendent of the Utica State Hospital, writes:

"My belief is that one must go back of the dentition, and regard the disturbance of this process as the mere exciting cause of the explosion."

Dr. Graeme M. Hammond says:

"I have records of several cases in which convulsions, due to dentition, were followed by true epileptic convulsions, and later by such dementia as we often see in children after repeated epileptic convulsions."

Dr. Frederick Peterson, who has given the study of epilepsy much careful attention, writes as follows:

"I can recall a number of cases of epilepsy due to the convulsions of dentition. Such epileptics might later on have mental disorders."

Dr. T. S. Clouston, Superintendent of the Royal Morningside Asylum, Edinburgh, a thorough and distinguished alienist, wrote as follows:

"I have seen cases of prolonged delirium ending in idiocy arising out of the convulsions of dentition. I have also seen many such cases ending in true epilepsy, followed by insanity. I have also seen so many cases of the insanity of adolescence and others occur in persons who had had severe convulsions when teething that I can scarcely regard the two as coincident."

I have the views of many others, but to reproduce them here would only be to add testimony of a similar nature to that already given. It would be a valuable lesson to learn, and having learned it, to remember it constantly, that the spasms and convulsions of infancy are *serious* manifestations, and if allowed to go unchecked, may lead to explosions of genuine epilepsy, and later on to insanity.

There is, as we know, such a thing as the epileptic habit. Epileptic seizures, once established or even initiated, have a strong tendency to remain permanent through no other apparent reason than the force and power of habit. Of course there is a reason why epileptic convulsions of idiopathic origin tend to repetition; but of this I hope to speak in a subsequent paper.

Bearing in mind the possibility of the establishment of the epileptic habit, we cannot lay too much stress on the importance of promptly relieving the distressing symptoms attending the eruption of the teeth in infancy. The importance of appropriate interference becomes more essential if there be an inherited tendency to mental disorder of any kind in the suffering child. The nervous system of the child is keenly sensitive to abnormal impressions of every kind. At this period of life it is the highest function of the nervous system to receive and register impressions.

Taking all these factors into consideration it would seem that the period of dentition, for a considerable class of children at least, might justly be regarded as an epoch—an epoch that invites epilepsy, with all its remote consequences, mental disorganization and mental death.

It is not necessary that I should speak of the therapeutic measures of relief that we can apply in such cases. I desire simply to call attention to the serious consequences that are likely to follow when the too-little regarded spasms and convulsions of infancy go unchecked.

Among other fruitful causes of epilepsy in infancy and childhood may be mentioned fright, blows and falls upon the head, acute diseases, intestinal worms, digestive disorders, and a generous variety of other causes which act reflexly, such as stricture of the urethra, adherent prepuce, and certain errors in the refractive and accommodative apparatus of the eye.

Fright, as a cause of epileptic convulsions which may be superseded later by true epilepsy, is most active before the age of seven and about the period of puberty. Up to the age of puberty it affects either sex about equally. At the period of puberty girls suffer most. This distribution is explained by reason of the profoundly disturbing effect the transition from girlhood to the higher plane of womanhood has on the entire nervous organization.

Head-injuries often lead to epilepsy, and, by reason of the usually limited area of the brain affected, the type of the disease is more frequently Jacksonian in character. Surgical measures constitute the only rational treatment in such cases. But, in order that good results be secured, they should be instituted as early as possible after the first warning that there exists an irritative lesion in the motor area of the brain that promises possibility of removal through operative intervention.

It sometimes happens that injuries received during childhood, and regarded as unimportant at the time, prove later in life to constitute lesions that give rise to convulsions. The lesion is acquired in consequence of inflammatory thickening of the membranes at the point of injury as a result of hyperplasia of the connective-tissue elements of the cortical layers of the brain. Surgical treatment in such cases does but little good. It is frequently necessary to excise a small portion of brain-substance in order to clear out as much as possible all tissue of foreign growth, and when the incision made by the surgeon heals, a scar is the result, which in time is capable of doing the very harm that was done by the original cicatrix.

Intestinal worms cause convulsions by reflex action, and it is important that the presence of such parasites be detected and that they be removed as soon as possible. Otherwise the epileptic habit is likely to become established.

Severe digestive derangement not infrequently gives rise to convulsions, especially in rachitic and puny subjects and in those that have an inherited tendency to nervous instability. Everything possible should be done to improve the constitutional vigor of such patients. Above all, the matter of diet should receive first consideration. I cannot pass over this part of the subject without briefly referring to the great value of intestinal antisepsis.

So long as there are errors in diet, and so long as faulty and inefficient digestive fluids are poured into the alimentary canal by reason of poor constitutional vigor and disease, and disorganized gastric and intestinal glands, just so long will be encountered fermentative and other processes that call for intelligent and active treatment.

Auto-infection is a common result in such cases, and, it having once arisen, the only way to deal with it promptly and effectively is to render the entire alimentary canal from end to end as free from the products of fermentation and putrefactive changes as possible. Lack of space forbids the further consideration of this part of the subject, and I shall now briefly refer to the very excellent provisions embodied in the colony-system in the care and treatment of epileptics.

It is not necessary that the history of the origin of this system of caring for the epileptic be reviewed. I shall merely suggest that anyone who wishes to familiarize himself with that branch of the subject should read an article by William Pryor Letchworth, LL.D., on "Provision for Epileptics," which was read before the National Conference of Charities and Corrections held at Nashville, Tenn., from May 23 to 28, 1894. The subject is also treated at length by Dr. Frederick Peterson in the *American Journal of Insanity* for January, 1894, in an article entitled "On the Care of Epileptics."

In 1873 the State Commission in Lunacy of New York called the attention of the Legislature to the necessity for some special provision for epileptics. No good came of their recommendations at that time. In 1878 the State Board of Charities referred to the subject, but their recommendations likewise bore no fruit.

Through its State Board of Charities, Ohio was the first State to adopt the colony-system. Efforts toward that end were begun in 1890, and on November 12, 1891, the corner-stone of this beneficent institution was laid at Gallipolis.

There is one very serious fault to be found with the Ohio colony, and that is its official name, the "Asylum for Epileptics and Epileptic Insane." "Insane" and "asylum" are both decidedly objectionable words. They should never be applied to institutions in which the sick are cared for and healed.

In 1892 Massachusetts sought to establish such a colony, but the Legislature of that State failed to take the necessary action.

The Lunacy Committee of the Board of Public Charities in Pennsylvania has been earnestly engaged for two years or more in trying to secure a "State institution" for the exclusive accommodation, care, and treatment of epileptics upon an industrial basis.

Michigan has enacted a law "providing for the care and treatment of epileptics and the feeble-minded in separate buildings on the cottage-plan."

In 1891 the State Commission in Lunacy in New York urged the establishment of a State hospital for the exclusive care and treatment of sane epileptics. Through the persistent and earnest efforts of the State Charities' Aid Association a bill was passed by the Legislature of this State in 1892, authorizing the State Board of Charities to "select a suitable site on which to establish an institution on the colony-plan for the medical treatment, care, education, and employment of epileptics, and to prepare plans and estimates of cost of buildings, and submit the same to the next Legislature." An excellent site, consisting of 1872 acres in the Genesee Valley, was found by the Board, and a bill providing for its purchase introduced in the Legislature in 1893. The bill passed with the almost unanimous indorsement of the members of the Legislature and general public approval. It was vetoed by the Governor for economic reasons. In a modified form the same bill passed the following Legislature and was approved by the Governor.

It was the original intention of the promoters of this great charity to call it the "Sonyea Colony," *sonyea* being an old Indian name signifying "sunshine." This was abandoned, however, after the death of the late Oscar Craig, at the time President of the State Board of Charities, and it was decided to honor that good citizen by naming the new home for epileptics "Craig Colony."

Briefly, it is the object of the colony "to secure the humane, curative, scientific, and economical treatment and care of epileptics, exclusive of insane epileptics." This means that widely diverse and common-sense methods and means will be employed to alleviate the suffering of the epileptic. It means that in addition to medical and surgical treatment, applied in accordance with the light of modern science, Nature, the great restorer, will have an opportunity to do her best. With an abundance of pure air, sunshine, hygienic surroundings, wholesome and well-regulated diet, and physical labor adapted to the condition of each one required to perform it, the beneficiaries of this great charity certainly ought to be rendered far more capable of enduring that which, after fair trial, cannot be cured. They will engage in industrial pursuits of all kinds; agricultural, mechanical, carpentering, cabinet-work, the canning and preserving of fruit, berries, etc., and it is expected that within the course of a short time the colony will be placed upon a self-supporting basis.

Two classes of cases will be received: State and private. It is provided in the law that creates the colony that the State shall pay annually a sum not exceeding two hundred and fifty dollars for the support of indigent patients. In addition to this, it is made incumbent upon the Supervisors of the County from which the patient comes to send to the colony annually the sum of thirty dollars for the purpose of providing the patient with clothing.

Private patients are to be admitted to the colony

by consent of the managers and superintendent upon substantially the same conditions that govern the admission of private patients to hospitals in general. If an epileptic becomes insane while an inhabitant of the colony, he is to be sent to the State Hospital in the district in which he formerly resided. Patients are to be discharged by the superintendent on the approval of the managers.

An excellent feature of that part of the law pertaining to the discharge of patients states that "no epileptic patient shall be returned to any poor-house directly through a superintendent of the poor, or otherwise."

The colony is to be governed by a Board of Managers appointed by the Governor. Each manager serves for five years. The managers are to appoint a superintendent, who must be qualified by the Civil Service Commission as to his fitness for the position.

This radical departure in the treatment of the epileptic ought to produce a rich harvest of good. By reason of his unfortunate malady the epileptic is not permitted to become a part of our social fabric. He is forced from society and from the church, and he is everywhere driven from positions of employment and responsibility whereby he seeks to gain a livelihood. Although he may suffer but slightly by reason of his attack, he is often forced to mingle with the inmates of almshouses and hospitals for the insane, and with the more wretchedly afflicted of his own class.

The colony-system in the care and treatment of this enormous class of unfortunate dependents promises happy results. Time, in other countries, has already demonstrated most conclusively its worth.

70 WEST EIGHTY-EIGHTH STREET.

SYPHILIS BY CONCEPTION.[1]

BY GEORGE DUFFIELD, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE DETROIT COLLEGE OF MEDICINE, ATTENDING PHYSICIAN TO HARPER HOSPITAL, ETC.

SYPHILIS is a disease worthy of the most serious thought and consideration by every specialist and general practitioner. The disease is on the increase, is widely diffused, and is to be found in all countries, owing to the utter lack of sanitary control. The cases seen in private, hospital or dispensary practice, and which leave our care as soon as the annoying symptoms have been relieved, either from ignorance or criminal carelessness go out to relapse and spread the disease broadcast among the innocent of the land.

In every large city there are hundreds of syphilitics with active contagious lesions who are daily in our streets, drinking at the public fountains, or using the one glass in an ordinary railroad car or steamboat, at which innocent women or children seek to quench their thirst, little dreaming that a virus ten thousand times worse than the poison of the rattlesnake lurks on the cup. I appeal to your sympathies to show you that one of the diseases with which we come in daily contact is in our midst to an alarming degree, and your children and mine may be exposed to this fearful contagion. Extra-genital syphilitic infection is much more common than is generally supposed. The cases in which the origin of the disease is a mystery, and cannot be solved by the physician, often come under this form of infection.

Dr. Myles Standish, in the *Boston Medical Journal* of recent date, states that the public towel found in workshops, railroad toilet-rooms, and public wash-rooms, is often infected with syphilitic virus, and reports two cases of the disease that could be traced to this source. In the first instance, a married man became infected, and though warned, infected his wife; in the second a brakeman became infected. In both the primary sore developed upon the eyelids.

> "The individual with syphilis, therefore, is not only in danger of communicating the disease in marital relations, and constantly does so, but is also likely to transmit more or less of the taint to the offspring if they survive, and is likewise a constant menace to society by virtue of the contagious character of the disease."[1]

The works of Hutchinson and others give abundant testimony to the dire effects on the progeny of those affected with syphilis:

> "It must be remembered that just as syphilis can diminish the viability of the product of conception, and cause the death of the child just before or soon after birth, so it causes loss of life earlier in conception, and gives rise to frequent abortion."

As has been stated, this mortality of fetal life is not the only ill that flesh is heir to when syphilis has been acquired; and such an inheritance is a curse indeed.

The case I am about to report is still shrouded in mystery as to the mode of infection and development.

About the middle of September, 1893, a man of vigorous constitution, strong, robust, aged thirty, consulted me for certain irregular, dark, hyperemic spots that had developed on the palms of his hands. At first they appeared as small, red points; they did not itch or cause any pain or irritation, and vanished on pressure, only to return as soon as the pressure was removed. The wrists, arms, face, and neck were white and free from spots like those on the palms. The hands were very heavily muscled, were strong and showed points of callus the result of work on galvanized iron. The man supposed that

[1] Read before the Michigan State Medical Society, Lansing, May 4, 1894.

[1] Bulkley: "Syphilis in the Innocent." 1894.

he had been poisoned by the iron or some of the tools or chemicals that he had been handling. I advised him to rest a few days and wash his hands in hot soda-water so as to remove all stains and grease. This he did, and the spots became bright rose-pink in color and irregular in shape. As I have always been suspicious of palmar eruptions, and fearing that I had a case of syphilis to deal with, I made a careful examination of the patient's body, throat, and nose, but with negative results. There was no history of having had a chancre, hard or soft, but there had been an attack of gonorrhea nine years before. Had the man contracted syphilis at that time, secondary symptoms would long before have manifested themselves. Being uncertain as to the condition present, I sent him to Dr. A. E. Carrier, who thought the eruption of an erythematous nature with possibly a syphilitic origin.

About the first of November the man called on me again. There were now a good many more erythematous spots upon the palms and also upon the wrists. A few dry, scaly patches appeared upon the scalp, upper lip and eyebrows, causing the hair, moustache and eyebrows to fall out. Upon the scrotum there were half a dozen spots of the same color as those upon his hands. Upon the prepuce there was a point that was thickened. This was not seen at first; not until it was taken between the thumb and finger was it appreciable that there was any change in the tissues. It was not sensitive, but was simply an induration without erosion. There was no discoloration, no secretion from it, nor had there been. The patient claimed that he had never noticed it himself—but I doubt his statement. He declared that he had never had any intercourse away from home since he had been married, nor had he had sore-throat or a mucous patch. His wife I had known for four years. She was twenty-seven years of age, and had had one miscarriage two years after her marriage, after carrying water and coal to the second story. She had never had a skin-affection, but three years ago had a severe attack of diphtheria, since which time she has been in fair health.

On December 20th the husband told me that his wife had become pregnant, the second time since their marriage, seven years before, and wished me to call and make the necessary examination and give needed directions. Personally I was anxious to make this examination, to see whether my suspicions were well grounded as to the husband's syphilis and whether or not he had inoculated his wife. The examination was made with great care. There was no vaginal discharge and had never been; there was no history of dysmenorrhea or displacement, no swelling of the vulva and no enlarged glands in the vulva or groins. There were no indurated points in the vagina. There was no rash, no sore-throat, no loss of hair; there was absolutely nothing to suggest that the woman had been exposed to or had absorbed syphilitic virus. The pregnancy had advanced about five and one-half months, the last menstruation having taken place in the early part of July. The fetal movements had been felt and the placental bruit was plainly heard.

On January 15th, 1894, the woman called at my office suffering from fever and sore-throat. The tonsils were swollen and red. All her bones ached, but more especially those of the lower extremities. She had severe headache at night. The temperature stood at 102.5°. The attack simulated one of severe tonsillitis complicated with rheumatism. The symptoms were suggestive of syphilitic fever, but there were so many symptoms wanting that I thought it best to wait until some positive sign should show itself. The woman was given a mild gargle, with salol and phenacetin, and in about four days the temperature had fallen to normal. With the subsidence of the fever red spots broke out on the lower part of the abdomen, which she thought resembled the spots her husband had had on his hands in the summer. In a day or two a bright-red rash appeared upon the abdomen, confining itself to the skin over the enlarged uterus. It did not extend to the thorax or the limbs. It was undoubtedly a syphilitic roseola. Mucous patches appeared upon the tonsils, the soft palate, the tongue, and the buccal mucous membrane, and slight glandular enlargement in the groins accompanied the rash. Dr. H. A. Cleland saw the woman in consultation at this time and confirmed the diagnosis. He thought that the husband's initial lesion had been in the urethra—or at least that it had been hidden. The symptoms as found in the wife were proof-positive of syphilitic infection. She was put upon a strong solution of mercuric chlorid until marked physiologic effects showed themselves, when she was given a pill of protiodid, gr. ¼. The mucous patches were touched frequently with the solid stick of silver nitrate. In a few weeks the rash and mucous patches entirely disappeared, and there has since been no return of syphilitic manifestations.

I hoped that thorough mercurial saturation of the mother might have a beneficial effect upon the child *in utero*, which was undoubtedly the source of the maternal infection. The treatment was continued for three months, but I failed to note any effect, unless it was that the child when born was alive. Nunn[1] says that in his experience the treatment of syphilis during pregnancy does not protect the child from congenital syphilis, but that when pregnancy has terminated, treatment is more successful.

Etienne[2] states that if treatment be employed throughout pregnancy, we may hope to obtain almost complete immunity from this infantile mortality.

In an article on "Hereditary Syphilis," W. Gilman Thompson[3] states that "when the father only is actively syphilitic, he usually transmits the disease to the child through the spermatozoa. This is called 'conceptional syphilis.'" Etienne states

[1] Medical Press and Circular, 1891.
[2] Annales de Gyn., April, 1892.
[3] Pepper's American Text-book of Medicine, 1893, vol. i.

that paternal syphilis is less injurious to the fetus than maternal syphilis.

Early in April I noted that the fetal heart-beats and placental bruit had become weaker, and that the movements felt by the mother were less vigorous, and therefore concluded that the child would be stillborn.

On April 7th, about 3 A.M., the waters broke while patient was asleep. The pains began soon after, were frequent and harassing during the day, but at 8 P.M. the os had dilated only an inch. The pains were very hard, but they made no impression upon the cervix, which appeared swollen and unyielding. The woman had been in labor twenty-four hours and still there was little dilatation of the os uteri.

Dr. W. P. Manton was called in consultation at about 2 A.M. He found a rigid os, dilated about two fingers, but not enough for the application of forceps. Hot douches were given and an hour and a half was spent in waiting for the dilatation, which would not take place, although the pains increased in severity. Pressure by the fingers inside the cervix finally caused sufficient dilatation to allow the introduction of a narrow-bladed forceps, the patient having first been anesthetized. The bones of the child's skull were very thin and could be easily indented by the finger; possibly this soft and unresisting head was one of the reasons why the dilatation of the cervix had not gone on more rapidly. During traction the cervix was drawn so far downward as to be visible at the vulva, and required to be pressed upward under the symphysis, as it greatly retarded the advancement of the head. After half an hour's hard work, with but slight advancement of the head, deep incision of the cervix was resorted to and delivery accomplished without further delay, the child being born alive.

The child's head was very pointed and the caput succedaneum large and conical in shape. The sutures of the skull were wide open, the fontanels very large, and the bones soft and yielding. The placenta was delivered by Credé's method, and was studded with syphilitic gummata of a yellowish-white color. The cord was long and thin and was wound once around the child's neck.

The child had an eruption on its body, especially under the arms and upon the sides of the thorax. The cervical glands were enlarged and the mouth showed mucous patches. The right eye, though cleansed at once, developed a catarrhal conjunctivitis. Within ten days after birth the child was covered from head to foot with an exanthematous rash—a syphilitic roseola.

The treatment of the child from the first has been by inunction, twenty drops of a 10 per cent. solution of mercury oleate being rubbed in twice a day with marked benefit, although since the physiologic limit has been reached there has been considerable colic following the inunction. On the twelfth day after delivery two small gummy nodules appeared on the occiput, showing the child to be in the tertiary stage; the fontanels are still widely dilated and also the sutures.

The mother has nursed the child, and the supply of milk has been large and satisfactory to the well-being of her offspring. No mucous patches have yet appeared upon the nipples.

Perhaps the treatment of the mother by mercury alone—when she was suffering from secondary symptoms—may be criticised by some, but the effect could not have been better. Not a single syphilitic symptom has reappeared. Potassium iodid has been withheld purposely, as it was thought that the secretion of milk would be better without its use, and so it has proved.

The question naturally arises: Was the syphilis of the newborn derived from the father or the mother? It is my opinion that the spermatozoa of the male contained the microörganism of the disease. The latest investigations on the cause of syphilis show that it is due to a microörganism, and Klebs, Birch-Hirschfeld, Lustgarten, and others have described a bacillus found in various syphilitic lesions.

In 1884 Lustgarten described a bacillus that he found in sections of syphilitic ulcers, and which he believed to be the specific agent in this disease. He described the bacillus as smaller than that of tuberculosis, and occurring in curved or straight forms, singly, in pairs and groups, but never as rods. It is never found free, but is contained in round cells. Other observers have verified the existence of the bacillus, but no satisfactory experimental evidence has as yet been adduced.[1]

As to when the paternal syphilis was acquired is still a mystery. It was undoubtedly due to sexual transgression, and at the time fecundation in the wife took place, the husband was saturated with the disease, which had never been modified by treatment. His spermatozoa must have been surcharged with the specific microörganisms or their spores, and their toxic effect was manifested in the fetus with terrible virulence.

Now that the mother is infected, the question naturally arises: From which source, father or child, did the contagion emanate? I think from the latter, because the syphilis of the baby is more advanced than that of the mother, and the mother's syphilis is of a lighter degree or more attenuated. Then, too, the lateness of the syphilitic fever in the mother must be considered—the fetus was five and one-half months old before the mother showed a symptom of infection.

Diday[2] believes that the mother does not become syphilitic through the placenta, but through the blood of the fetus begotten by a syphilitic man.

The large gummata of the placenta on the side of the child show almost conclusively that the latter

[1] Sternberg's Bacteriology.

[2] Archives de Tocologie, 1891, No. 11.

was syphilitic long before the mother, and proved itself to be a hot-bed of infection, the microörganisms easily passing from the diseased placenta to the innocent mother. The absence of all initial symptoms in the mother, it seems to me, is conclusive of the conceptional transmission.

The tendency and frequency of abortion in syphilitic mothers is a point of interest that should be mentioned here. Etienne states that the mortality of the fetus in cases in which the mother has never been under treatment is enormous, reaching 95.5 per cent. Abortion occurs in about two-thirds of all syphilitic women—that is, when the women are primarily affected and have skin-eruptions and mucous patches at the time of conception. If infection of the fetus occurs during the first three months, and is not subjected to treatment, the mortality during the first few days after delivery reaches 100 per cent.[1]

The chances for a premature discharge of the fetus when the father alone is syphilitic are considerable, but this does not occur so frequently as when the mother is primarily affected. Neumann states that if the father is syphilitic, and the mother first becomes so in the later months of pregnancy, the hereditary syphilis in the child will be intensified.

Recent notes on 1127 pregnancies, collected by Fournier, show that the infantile mortality, when the disease is inherited from the father alone, is 28 per cent.; when from the mother alone, 60 per cent.; when from both parents, 68 per cent. Le Pileur claims that not over 7 per cent. of the children of syphilitic parents outlive the disease.

Fournier attended a family in which the first three children were born at term, robust and healthy. The father then contracted syphilis, and his wife, becoming infected, aborted three times in succession. Fournier also reports that at the Lourcine Hospital 145 out of 167 of the children born of syphilitic mothers died in the institution within six weeks after birth. From trustworthy statistics of 441 cases only 100 children who had syphilitic mothers survived infancy, while 341 perished, 335 dying during the first year of life, and only six surviving this period.

Professor Chambrelent,[2] of Bordeaux, reports the case of a young married woman who contracted syphilis during her second pregnancy, but who had no initial lesion.

I know that some observers claim that infection of the fetus is more rapid than that of adults, partly from the fact that the new tissues resist less, and the blood, being so saturated, carries the disease into vital organs more rapidly than in an adult.

A fetus that develops and passes through the first and secondary stages of syphilis, and enters the tertiary period, all within 285 days from conception, displays a great shortening of the periods of the disease, and plainly demonstrates that inherited syphilis is much more virulent than is acquired syphilis in the adult.

The duration of syphilis is still a matter of discussion. Thompson puts the duration of the initial lesion at six weeks, the secondary symptoms at from two months to three years, and the tertiary period as beginning between the third and sixth years, and lasting for twenty years or more.

When the treatment has been systematically carried out for two and one-half, or better, three years, and there is no return of symptoms within six months, the patient may be regarded as cured, and he may marry without endangering mother or offspring.

The transmission of syphilis by mothers who have the disease, even though they have been under treatment, is well illustrated by Nunn,[1] in the case of an infected woman aged sixty, whose daughter gave birth to an infant with symptoms of syphilis. The father of this infant could not be proved to be syphilitic. The case shows that syphilis is transmitted even to the third generation.

CLINICAL MEMORANDA.

TWO CASES ILLUSTRATING THE IMPORTANCE OF COMPLETELY EMPTYING THE UTERUS IMMEDIATELY AFTER MISCARRIAGE; OPERATION FOR ABDOMINAL EXTRA-UTERINE PREGNANCY AND REMOVAL OF FIBROMA OF UTERUS.

By EDWIN K. BALLARD, M.D.,
ASSISTANT SURGEON TO HOSPITAL FOR THE WOMEN OF MARYLAND, BALTIMORE.

Case 1.—Some months ago I was called to see B. F., about thirty-five years old, a colored woman, married, and the mother of four children. She complained of having felt badly for some time, perhaps two weeks or more. She did not present any symptoms of definite trouble, but merely said that she was not as well able as usual to do her work, felt weak and had some headache and a poor appetite. Questioning failed to elicit anything more definite upon which to base a diagnosis; so a tonic was prescribed, and a second visit promised in about a week. At the end of that time I found her feeling and looking much worse, with a temperature of about 101°, and stating that she had had slight chills. The pulse was somewhat rapid, and symptomatically the case looked like one of malarial fever; so five grains of quinin were prescribed three times a day, with a suitable dose of calomel at night.

At my next visit, soon afterward, I got a more com-

[1] The Medical Press and Circular, No. 2742, 1891.

plete and truthful history, and one that began to point to the cause of the trouble. The woman then told me that about three or four months previous to my first visit she knew herself to be pregnant, as evinced by well-known symptoms that had become familiar to her in several previous experiences. Everything went well until within a number of weeks before my first visit, when she had suffered a sudden and profuse flooding, losing a large quantity of blood, and passing very large lumps, which she could not describe more accurately than that they were large and looked like liver or flesh. After the hemorrhage her abdomen began to diminish in size, the invariable sensations felt during her pregnancies left her, and in their stead ill-health had crept on; her weight had decreased, and, varying in quantity and constancy, the bloody discharge had continued and grown more unendurable by acquiring a very offensive odor.

I carefully explained the seriousness of her condition, that she had evidently miscarried at the time of the flooding, but that her womb certainly contained something to keep up the bleeding, and which was poisoning her. Permission for an examination was asked, with the comment that an operation would no doubt be required. Though daily growing worse, the woman flatly refused to allow a vaginal examination, and requested something for the discharge. With regret at her stupidity, I ordered an antiseptic vaginal douche, feeling sure she would eventually yield in preference to the risk of dying. After a few more days, during which her pulse grew weaker and her temperature remained several degrees above normal, although she was fully under the influence of quinin, she consented to an operation, provided no preliminary examination be required. The indications by this time were so plain, in fact, so urgent, that I determined to go ahead without an examination beforehand, or, after getting her under chloroform, to abandon the operation if it were unnecessary.

When the operation was begun the os uteri was sufficiently dilated to admit a finger, and discharging from the cavity of the uterus an offensive fluid mixed with shreds of decomposing tissue. The probe passed without resistance to the depth of seven inches, a fact that surprised me, as I expected to find the uterus more contracted after such a length of time from the supposed miscarriage. The cervix was then dilated and the uterus thoroughly and carefully curetted, removing a quantity of broken-down membrane and other tissue, until the curet failed to bring away any more and grated against the firm uterine wall. The uterine cavity was next gently syringed with warm carbolized water, and I was preparing to mop it with an antiseptic astringent when the uterus gave a spasmodic contraction of some violence, and to my astonishment a tiny white foot presented through the external os. I seized it with forceps, withdrawing it and a leg, and continuing with the use of forceps and curet, until a whole fetus, three inches long, was delivered in sections. A second fetus followed the first, and was removed in like manner, after which the uterus was found contracted down to a size of about four inches, and I felt sure it was empty. It was again irrigated and swabbed out with a solution of Monsel's solution and carbolic acid in glycerin. Following the operation, the patient's temperature immediately began to decline, and in two days was normal. The discharge, which had continued about a month, ceased, and she made a rapid and perfect recovery. She has been in good health ever since, and, in addition, has been delivered of a healthy infant.

This case and the following one illustrates, among other practical points, with what tenacity and persistence the uterus at times retains bits of membrane, or even a whole fetus after its death. And they also point to the only rational and safe treatment of such cases, viz., immediate and complete emptying of the uterus. If hemorrhage continue after miscarriage, it is dangerous folly to temporize with the use of ergot and other drugs in the expectation that a serious condition will right itself. There is a possibility that it will, if let alone, as in a number of other pathologic states, but it is the duty of a physician, both to his patient and himself, to aid Nature by the speediest and safest methods; and to neglect a miscarriage is neither, but is a direct invitation to hemorrhage, sepsis, inflammation, and similar evils that often lead to chronic invalidism or death. As in these two instances, patients will from various motives intentionally or ignorantly conceal facts from their attendants, causing them to grope in the dark or be entirely misled, but they should persistently search after causes, and a direct physical examination, not only after suspected miscarriage, but in a number of obscure affections, will be a simple procedure, as well as prove a revelation, which endless questioning could never elicit.

CASE II.—Miss L. T., twenty-one years old, was a patient at the Hospital for the Women of Maryland in 1892. Soon after her discharge she was married, and in about three months, during the course of a miscarriage, she hastily summoned me one night, the messenger, a member of her family, saying that she was bleeding profusely. Upon arriving at the house I found her lying on a sofa downstairs, having been suddenly taken with a flooding, and unable to reach her bedroom. As it was time for her menstrual period, and she was suffering somewhat the same as she had at previous periods, except that the flow was more profuse, she refused to allow a vaginal examination, though urgently advised to submit to one. After close questioning I concluded she must be undergoing a miscarriage, and so expressed my opinion to the family, but the patient obdurately refused to permit an examination. She was then quite weak from the loss of blood, and in the course of four days, her condition having become alarming, and the hemorrhage still continuing, she agreed to an examination. The os uteri was found widely dilated, and an irregular mass blocking it up. The patient's condition at this time was bad, with evidences of septic infection. On the next day I thoroughly curetted the uterus, removing a quantity of offensive decomposed membrane, after which the uterine cavity was irrigated with a carbolized solution and mopped out with diluted Monsel's solution and carbolic acid. The dangerous symptoms receded immediately after this operation, and the woman made a good recovery, though convalescence was slow.

For several years previous to this the patient had been subject to constant pelvic pains, which progressively grew worse, and were found to be due to inflamed and prolapsed ovaries. The removal of these organs was advised, but before deciding whether or not to accept

operation the patient again became pregnant. All the symptoms of pregnancy, including troublesome nausea and vomiting, continued for three months and then ceased. The patient's former suffering also ceased, and she felt better than for a number of years. As time passed, no abdominal enlargement occurred, as was expected, and it became a question as to the cause of such a change in her feelings, both regarding pregnancy and the state of her general health, which was good.

A vaginal examination, made about five months after the symptoms of pregnancy began, did not throw much light on the subject; the ovaries were prolapsed and painful as before; no signs of pregnancy, and no abdominal enlargement were present, and no tumor could be discovered by palpation. Menstruation had ceased for five months, and a probe was not passed. The woman was advised to await developments, and to do nothing unless there seemed to arise some reason for interference.

Six months after the last menstruation I was again summoned, and found the patient in great pain, and passing blood. Though this was the date of expected menstruation, this time she made no objection to an examination, and I found a round object protruding from the mouth of the uterus. Upon removing this with my finger her pain ceased at once. An examination proved the object to be a uterine mole the size of a lemon. Then, of course, the behavior of the case was immediately cleared up; the patient had become pregnant; death of the fetus occurred after a certain time, and instead of being expelled, as is usual, it degenerated into the rare phenomenon of a so-called uterine mole, expulsion eventually following. To feel sure that the uterus had been emptied of its contents—and it is a point to be especially noticed—though everything seemed to have passed, I curetted the cavity of the viscus, removing a few small fragments of membrane. Recovery from the miscarriage was prompt.

The pelvic pains returned in a short time with increased severity, rendering the woman unfit for her duties or for pleasure, and as she was rapidly declining in health, removal of the ovaries was again advised. On May 15, 1894, at the Woman's Hospital, I removed both ovaries and oviducts. The left ovary was almost entirely destroyed by a cystic growth. Previous to operation there had been some uterine hemorrhage for two or three weeks, and the uterus was somewhat enlarged, presumably from subinvolution. Following the passage of the mole, menstruation had recurred at regular intervals. Six days after the oöphorectomy, though the patient had been progressing favorably in every respect, she was seized with violent abdominal pain, and by a vaginal examination a small mass was found presenting at the dilated mouth of the uterus. The clearing away of some clots relieved her pain at once, but the mass could not be removed by my finger. The condition of the patient suggested that at the time of operation a pregnancy in its early stage had been overlooked, though that seemed impossible.

The patient was again chloroformed, the protruding object removed with forceps, and the uterus thoroughly curetted, some very strongly adhering bits of membrane being scraped out. The mass proved to be not a recent embryo, but a thick fragment of membrane remaining from the passage of the mole, despite the precautionary curetting three months before the time of the last operation.

Beyond a moderate amount of shock, the curetting did not unpleasantly affect the patient, nor in any way disturb the favorable progress of affairs after celiotomy. The presence of the retained membrane explained the cause of the uterine enlargement preceding the celiotomy, as well as the metrorrhagia. In a similar future case I should curet a second time *before* performing celiotomy, and not risk compromising results by ignoring the possibility of a necessity for curetting so soon after a capital operation. In this instance, however, I felt so sure that the uterus was empty that the curetting did not seem necessary.

CASE III. *Extra-uterine pregnancy complicated by uterine fibroma.*—The patient was a colored woman, forty-five years old, married, and the mother of eleven children. When first seen by me, and at the time of operation, her history was that she had been in bad health for over a year, and had an abdominal enlargement. She was very weak, and for some time had been unable to work. Questioning elicited no further information beyond the fact that about a year previously she had missed her menstrual period once or twice, after which she became regular, as usual. Being near the menopause, and not presenting special symptoms, this slight irregularity of menstruation did not seem of importance. Upon physical examination a mass the size of a small cocoanut was found in the pelvis and attached to the uterus, which was not much beyond the normal size. On palpation through the thin abdominal walls a large irregular tumor could be felt, apparently a fibroma, but which possessed the peculiarity of a slightly movable, angular projection from its surface, which I remarked as rather unusual to occur in a fibroid. By bimanual palpation through the vagina the mass in the pelvis and the lump in the belly were found to form a single body, freely movable by pressure brought to bear against one or the other alternately; nor was there anything to indicate that the whole was not an individual solid tumor.

My opinion, based on the single examination and what little history was given, which amounted to nothing, was that the patient suffered from a uterine fibroma that had existed a much longer time than she imagined, as no symptoms other than abdominal enlargement had attracted her attention. Her condition urgently demanded relief, especially as she was obliged to earn a living, and after a full explanation to her and her husband that it was uncertain what could be accomplished, if anything, and also that the operation was very dangerous, both consented to risk it.

The place of operation was unique and picturesque, but by no means convenient, its chief advantage, and a very important one, being an abundance of pure air. The woman lived in a small one-room log cabin on a mountain top, commanding a view for miles across a lovely and historic country. An old door, full of shot from former target-service, laid across a chair and table, formed an operating-table. The place of a sterilizer was substituted by an old iron pot, over an open fire outside of the house, which did not boast of a stove. The male members of the family attended to the pot and furnished hot water on demand.

The attending physician had ordered the house to be

scrubbed and whitewashed; ventilation was ample, and under the circumstances the surroundings were as favorable as they could be made, and beyond its surgical aspect the operation was one of more than ordinary interest. The patient had been properly prepared.

Through a long abdominal incision the state of affairs was much more plainly seen than could be reasoned out or determined in any possible way before the operation, as is so many times true in intra-abdominal surgery. Instead of simply a large fibroid of the uterus, it developed that in addition, we had to deal with an abdominal extra-uterine pregnancy. Enclosed in a thin sac was a fetus weighing about five pounds, that had been dead for a considerable time; the sac, firmly adherent to all surrounding viscera, forming with its contents and the uterus and a fibroid growing from the uterus, a large, consolidated tumor.

Through an opening made into the sac, the fetus was easily lifted out, and then it appeared that its natural attachments were absent, there being no placenta and no umbilical cord, this organ being represented by a slight knob on the child's abdomen. The fetus itself was much distorted, and its limbs and body firmly glued together by dense organized adhesions. The fate of the cord and placenta was merely a matter of speculation; they could not have escaped detection, as the whole abdominal cavity and its contents were open to plain view.

The removal of the sac was not such an easy and safe proceeding. The bowels and other viscera were densely adherent to it, but by carefully separating the adhesions with the finger-nail and ligating and then cutting away sections of the sac when necessary, the whole was removed without troublesome hemorrhage or injury to the viscera.

Having disposed of the sac, the fibroid was attacked. Its pedicle was round, with a web-shaped projection that was ligated separately, and then the main pedicle carefully ligated with very heavy Chinese silk. The tumor was cut off and its stump freely mopped with Monsel's solution. The fibroid proved to be cystic. Considerable oozing took place from the torn surface of the adhesions, but ceased upon pressure and the free flushing of the abdominal cavity with boiled water. The pedicle was left within the abdomen, the wound closed with silk sutures, and for fear of future hemorrhage, as oozing had been free, a glass drainage-tube was inserted, though I should have preferred not to have been obliged to use it.

There was no noteworthy shock during the operation, and almost as soon as she was put to bed the patient awoke and wanted to talk. She suffered no nausea or pain, and, considering the severity of such an operation on an ill woman, the outlook seemed promising. At my visit in the afternoon she was comfortable. That ended my personal care of the patient, but after my return to Baltimore her physician reported in a day or two that she was doing well; the drainage-tube had been removed, the bowels had moved, the temperature had become normal, and the patient was anxious to eat, and comfortable in every way. Five days following the operation, however, she began to fail, and at the end of a week died. The wound healed, and all seemed to progress favorably until a few days before death, the cause of which was not satisfactorily determined, but may have been due to septicemia or exhaustion preceding and increased by the operation.

855 PARK AVE.

A CASE OF URTICARIA WITH COINCIDENT GLYCOSURIA.[1]

BY EMMA L. BILLSTEIN, M.D.,
OF PHILADELPHIA;
DEMONSTRATOR OF HISTOLOGY IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA; CLINICAL ASSISTANT IN THE DEPARTMENT OF SKIN-DISEASES, PHILADELPHIA POLYCLINIC.

A DISEASE like urticaria, of which the essential feature is instability of the vasomotor nerves, paroxysmal in its manifestations, and in which the paroxysms are induced by intrinsic or extrinsic irritation, mechanical or chemic, acting centrally or peripherally, may have its origin in widely different and in remote and obscure derangements of the organism; while the occurrence of pathologic conditions and processes, each in itself sufficient to account for the disorder, and each intensifying the morbid influence of the other, may make it difficult to determine the ultimate etiologic factor.

Owing to the physiologic relation between the skin and the alimentary canal, disturbance of the latter is a common element in disease of the skin, and probably the most frequent cause of urticaria. Glycosuria, on the other hand, while it is known to give rise to various pruriginous eruptions, is one of the less common causes of this common lesion. Kaposi[2] enumerates this affection among the dermatoses diabetica, and Crocker, in his text-book on *Diseases of the Skin*, mentions glycosuria in a long, classified list of causes of urticaria.

In the case about to be described gastro-intestinal derangement, with all its complexities, was still further complicated by the presence of sugar in the urine. The patient, a lad eleven years of age, came to Dr. Cantrell's clinic at the Philadelphia Polyclinic Hospital, February 27, 1894, accompanied by his mother, and from her the following history was obtained.

Both parents are living and well. The patient has three brothers, all in good health. The youngest, four years of age, was then under treatment for eczema, but otherwise was well, as his bright, rosy face amply testified. The paternal grandmother had rheumatism, and a paternal uncle died of chronic nephritis induced by exposure while intoxicated. No other member of the family has ever had urticaria.

The patient is slender and fair, and has naturally a somewhat fragile appearance, to which a striking pallor and conspicuous blue veins about the temples lend an exaggerated effect. When he was two years old he had an attack of measles and since then he has been "delicate." Prior to this he was vigorous. Between three and four years ago he had an illness which was pronounced "malaria" by the attending physician. For two years past he has had urticaria. He is troubled with dyspepsia and constipation, complains of headache and vague pains in the limbs and elsewhere, is easily fatigued and is very sensitive to cold. He is also subject to "nervous spells," as his mother expresses it, of

[1] Read before the Alumnæ Medical Society, June 9, 1894.

[2] Wien. med. Presse, 1883, No. 23.

two and three days' duration, which are characterized by great restlessness, followed by an apathetic and drowsy condition. They are ushered in by severe headache, but otherwise are unaccompanied by distress, and appear to have no causal relation to the urticaria.

On his first visit the patient had a few pink wheals on the arms—all that remained of a profuse eruption that had appeared on his getting out of bed that morning. Factitious wheals were easily produced by local irritation. The efflorescence was said to be usually most abundant on the extremities, and to consist of "spots and bumps," varying in superficies from a pin's-head to a dime. As a rule, not a trace of it remained when he arrived at the clinic. On two occasions there was a papular eruption on the hands and wrists, with here and there a large white wheal with an encompassing pink halo, and several small patchy areas of hyperemia. The paroxysms were not observed to occur after meals, and do not appear to be associated with the taking of any special article of food, but exposure to cold was invariably followed by an evolution of wheals.

The itching was most intense just prior to the appearance of the eruption, and the boy's remark that "It doesn't itch when it's all out," bears out Jacquet's reversal of the old formula: "Ce n'est pas l'eruption qui est prurigineuse, c'est le prurit qui est eruptif."[1] The patient complained of his skin feeling dry and uncomfortable; it was, however, soft and smooth to the touch, and frequently bedewed with moisture, and his sensations were probably due to the anemic condition of the tissue and its saturation with sugar.

The chronicity of the urticaria, and the frail, depressed condition of the patient, led to a careful and extended investigation of his case. Physical examination yielded negative results. The complaint of headache suggested that the eyes might be at fault, but the ophthalmologist reported in effect that nothing was amiss with the eyes; a slight refraction-error, not sufficient to require lenses, being the only departure from the normal. In an examination of the blood the estimate of hemoglobin was 75 per cent., showing that the boy's extraordinary pallor was only partly caused by the anemia which it suggested, and was perhaps mainly due to an unequal distribution of the blood—in this case to determination of blood to the abdominal splanchnic vascular area, in consequence of chronic digestive disturbance, which sometimes gives rise to a very pale and anemic skin without any deficiency in the hemoglobin. Analysis of the urine revealed the presence of sugar. The specific gravity was 1026, and all the physical properties were those of saccharine urine. A suitable regimen was thereupon advised, but as subsequent analysis gave only a partial reduction in the amount of sugar, probably because instructions were not closely followed, codein, in conjunction with strychnin and quinin, was prescribed. Under the influence of this combination the sugar promptly disappeared and the specific gravity declined to 1018. Quantitative analysis made prior to the administration of codein, but after the patient was on a diet from which starches were largely and sugar entirely excluded, gave 0.9 per cent. of sugar.

[1] "On the Pathogeny of Urticaria, etc.," Gazette des Hôpitaux, 1892, lxv, 1259.

Polyuria and concomitant symptoms of diabetes were wanting, and the progress of the case was contrary to that of this grave constitutional disorder in children, which is rapidly from bad to worse. So far as could be learned, there was no hereditary influence to account for the glycosuria, nor could a history of somatic or psychic trauma be obtained, and it must be regarded either as a transitory functional disturbance, such as is said to be not uncommon in markedly neurotic persons, or as a "paroxysmal neurosis" corresponding to the uric-acid shower in persons having the gouty diathesis, and sometimes occurring together or alternating in the same individual.

Examinations of the urine were made at regular intervals during the twelve weeks the patient was under observation, and it remained free from sugar both during the administration of codein and also after its discontinuance. The sediment was always inappreciable in amount, but the patient's mother said that at times there was a "red, sandy settling"—probably uric acid. Boiling almost invariably precipitated a cloud of calcium phosphate. In another case of urticaria, in a colored woman who presented herself at the clinic at the same time, analysis of the urine was attended with similar results—sugar and phosphates were in excess. (Further observation was not made in this case, as the patient did not return.) Phosphaturia is not uncommon in dyspepsia, and J. F. Goodhart,[1] in a paper on "Transient Glycosuria of Neurotic Origin," mentions a case in which the glycosuria was accompanied by persistent phosphaturia.

Urticaria usually grows worse on the approach of warm weather, but, nevertheless, with the complete disappearance of the sugar from the urine the patient began to improve. The intervals between the paroxysms lengthened, and the pruritus diminished, this giving him so little annoyance now that he no longer takes the trouble to apply the phenol-lotion that he previously used with benefit. Although the spontaneous eruption appears only every two or three days, instead of two or three times a day, as before, the cutaneous irritability persists, and factitious wheals are as readily provoked as at first. Letters or figures traced with the finger-nail or other suitable means stand out in strong relief against the surrounding skin as white, raised lines, with hyperemic borders. The irritation (the writing) is followed by a momentary linear pallor replaced by a faint red line, which in a few seconds becomes white and prominent, while at the same time parallel pink zones develop on either side. The white line has the appearance, and gives to the touch the impression of a hard, distended vein, or of a cord just beneath the epidermis, lifting it. It may be seen to swell for from four to five minutes, and synchronously the hyperemic zones broaden, their width depending on the vascularity of the part. The phenomena are said to correspond to a transient initial dilatation of the capillaries of the affected area, quickly followed, first by spasmodic contraction, and then by paralytic dilatation, with serous exudation into the papillary layer. The development of the factitious wheal is usually accompanied by tingling and heat, but in this case subjective sensations were not experienced; the

[1] British Medical Journal, 1889, ii, 1381.

patient said he should not be aware of the wheal if he did not see it. The central edematous portion is analgesic, from the benumbing pressure of the exudate on the sensory nerves, and the patient could not distinguish the point from the head of a pin applied to it. The hyperemic zones are said to be hyperesthetic, but in this case they did not appear to be any more so than the adjacent normal skin. These wheals, like those which appear spontaneously, are evanescent; their average duration is half an hour, but they may persist for one, two, or three hours, and exceptionally for a much longer time, as in this case, in which, on one occasion, letters traced over the sternum at four o'clock in the afternoon had not entirely faded at nine o'clock the next morning. Cases are on record in which the wheals lasted twenty-four hours, and even two days. The vasomotor instability is usually heightened by warmth, but it is noteworthy that in this case the special factor in its exaltation is cold. On the occasion just referred to, when the factitious wheals were so persistent and the irritability was so excessive that mere contact was followed by an urticarial blush, there had been a sudden fall in the temperature the previous night, and the day was comparatively cold. Bronson[1] records a similar case, occurring in a woman in whom a paroxysm took place whenever the temperature was suddenly lowered, and who was always worse in cool, damp weather.

This unstable equilibrium of the cutaneous sensomotor nerves, in virtue of which wheals can be excited by local irritation, constitutes the dermographism of French writers, otherwise urticaria factitia. Barthélemy, who has recently made an exhaustive study of this condition, while he admits the clinical and anatomic identity of the induced and the spontaneous wheal, is of the opinion that urticaria and dermographism are not the same, and that even when they coexist and are due to the same cause they are, nevertheless, independent of each other. Dermographism he regards not as a disease *sui generis*, but as a state of the nervous system in which it is peculiarly susceptible to impressions—that is, to toxic influences. Two conditions are essential: (1) an irritable and excitable nervous system, innate or acquired; and (2) a toxic agent that affects the peripheral vasomotor nerves (cutaneous theory), or the centers in the cord and medulla (bulbar theory). Hysteria and the arthritic diathesis are supposed to determine a state of the nervous system favorable to dermographism, though, of course, this may occur in the absence of both. Mild and intense forms are recognized, the chief factor in the grade being the susceptibility of the nervous system and not the severity of the intoxication. Finally, this condition, "a genuine intra-cutaneous manifestation of hysteria," Barthélemy suggests, though not in itself serious, is an evidence of an established intoxication, of diminished resistance on the part of the nervous system, and is never found in health. It occurs in many diseases, especially those giving rise to auto-intoxication, is common in dyspepsia and neurasthenia, and exists in every case of genuine urticaria. Barthélemy also states that he has seen it in six cases of diabetes. The same author calls attention to the influence of toxins on the vasomotor centers, as demonstrated experimentally by Charcot and Bouchard.

Intravenous injection of a secretion-product of the bacillus pyocyaneus, called anektasin, by its inhibitory influence on the chemotactic susceptibility of the plasma, will prevent local non-inflammatory edema and even inflammatory edema. A contrary effect is obtained by ektasin, a ptomaïn isolated from tuberculin, which stimulates the vaso-dilator centers and augments vasomotor reaction, with consequent dilatation of capillaries, stasis, serous exudation, and diapedesis; and the circulatory ataxia in urticaria is explained on the supposition that toxins occurring in the organism, those of the alimentary canal in particular, have a similar action. On this view the latency of the disorder is comprehensible, and also its localization, when we remember that the dilator fibers govern local areas and do not influence the general circulation. The nervous system is charged, so to speak, and it needs but a touch to evoke a manifestation. More recently S. Mackenzie, in a clinical essay entitled "On the Nature of Urticaria,"[1] suggests that the distribution may be accounted for by stimulation of the nervous plexuses of the skin by *something* in the circulation, possibly a "metabolic by-product."

When for any reason digestion is delayed, and the ingesta remain too long in the several divisions of the alimentary canal, there is abnormal fermentation and putrefaction, with the development of toxins, to which not only the disordered function of the cutaneous vasomotor nerves may be ascribed, but also the headache, languor, and general *malaise* of which this patient complained. That the glycosuria served incidentally to aggravate the urticaria there can be no question, as the disappearance of the sugar from the urine was followed by very decided improvement; but the gastro-intestinal derangement still dominates the case, and probably was the cause of the skin-disease in its incipiency, as it is now that which perpetuates it. Another view might be taken, which in nowise controverts the foregoing. The glycosuria, the digestive disturbance, the "nervous spells," and so forth, may all be dependent on the gouty diathesis, which is certainly suggested by the patient's hereditary and clinical history, and which, then, is also the underlying cause of the urticaria.

HEPATIC ABSCESS.

By GEORGE TULLY VAUGHAN, M.D.,
PASSED ASSISTANT SURGEON U. S. MARINE-HOSPITAL SERVICE.

The following cases of abscess of the liver occurred in my practice while stationed at Evansville, Indiana, in charge of the marine hospital at that port. In none of the cases could any history of malaria or of dysentery or other bowel-trouble be elicited, so that they must be classed etiologically as idiopathic.

The causes of hepatic abscess usually given are:

1. The ameba coli in cases of dysentery.

2. Suppurative inflammation in other parts of the body, especially in connection with the portal circulation or the branches of the inferior vena cava, as ulceration in typhoid fever, colitis, proctitis, appendicitis, pelvic and perineal abscess, and hemorrhoids; also septicemia and

[1] Brit. Journ. of Dermat., 1894, vi, 65.

pyemia, and injuries to the skull and other bones, producing osteomyelitis.

3. Foreign bodies and parasites, as gall-stones, needles, fish-bones, etc., from the alimentary canal, the ascaris lumbricoides, echinococcus, and tubercle-bacillus.

4. Traumatism, the skin not necessarily being broken.

5. Idiopathic, when, the cause being unknown, the disease is attributed to excessive heat, sudden chill, malaria, or the excessive use of alcohol.

Climate, race, age, and sex are to be considered as predisposing causes. Tropical and subtropical countries furnish most of the cases. The condition occurs in the negro as well as in the white man, but I cannot say which is the more predisposed. The large majority of cases occur during the active period of life—from twenty to fifty years of age. Sex is a very important factor, as it appears from the statistics collected that only about 3 per cent. of cases occur in women. As stated by Professor W. C. Dabney, the most important symptoms are directly connected with the liver, such as swelling, pain, and tenderness on pressure in the hepatic region. These symptoms, with irregular chills, fever, and sweats, give strong presumptive evidence of abscess of the liver.

According to Cyr, quoted in Sajous' *Annual*, if the abscess is located in the convex part of the liver, there is dyspnea and marked pain radiating toward the chest and shoulder, seldom jaundice; if located in the center, there is absence of local symptoms, but decided jaundice if the abscess be large; and when seated near the under surface there is an absence of thoracic symptoms, but stomach troubles, such as vomiting, are likely to exist. Chyluria is a symptom that should be remembered, in order to exclude pancreatic and hemato-parasitic diseases. It was not observed in any of my cases.

Without doubt the proper treatment is early incision, with free drainage, under aseptic conditions. Of six cases that I have seen treated in this way (including my own three), five recovered, and the sixth would probably have done so had not the operation been delayed until the abscess had opened into the right lung. The abscess-cavity was not irrigated in my cases. The pus being sterile, as a rule, irrigation seemed unnecessary, and I have seen it produce unpleasant symptoms.

Case I.—F. P., a white boatman, twenty-six years old, was admitted to the hospital on February 27, 1891, having suffered for five weeks with severe pain in the region of the liver, with irregular chills, fever, night-sweats, occasional vomiting and a dry cough. The bowels were constipated. There was no history of malaria or dysentery, but the patient had used alcoholics steadily for several years. There was evident tumefaction in the epigastrium and right hypochondrium, most marked at a point midway between the navel and the cartilage of the right ninth rib, where also the pain and tenderness were greatest. The liver-dulness in front extended from the fifth rib to the level of the umbilicus.

The stools were light in color, the urine dark, and thought to give a slight bile-reaction with chloroform, though it gave none with Gmelin's test.

For three weeks after admission to the hospital there was little change in the symptoms. The temperature, taken in the mouth, ranged from 37°–37.3° C. in the morning to 37.5°–38° in the evening; but the pain grew worse, requiring large doses of morphin for relief. It not being clear whether the case was one of abscess of the liver or one of obstruction of the cystic duct or bile-ducts, exploratory celiotomy was considered justifiable.

Chloroform was given, and under aseptic precautions an incision fifteen centimeters long was made through the skin and fascia from the most prominent part of the cartilage of the right ninth rib downward, parallel with the linea alba. The muscles were divided to the extent of ten centimeters, down to the peritoneum, which was found thickened, but not adherent to the liver.

All bleeding was arrested, and the peritoneum opened by an incision eight centimeters long, bringing the liver into view. Two fingers were introduced, and, as far as they could reach, the liver was felt, giving the sensation of a fluctuating tumor with thin walls. As there were no adhesions the visceral and parietal layers of peritoneum were stitched together with catgut, thus closing the peritoneal cavity and leaving about five centimeters of liver-surface exposed at the bottom of the wound, which was packed with iodoform-gauze and dressed. The next day firm adhesions were found to have formed, effectually sealing the peritoneal cavity. A knife was thrust into the liver, with the expectation of inducing a large outflow of pus, which, however, failed to appear even when the instrument had been inserted to the depth of two and one-half centimeters.

A large aspirating-needle was then tried, and at the depth of seven and one-half centimeters about sixty cubic centimeters of bloody pus were withdrawn. A finer needle was introduced in various directions in the liver-substance, to the depth of from five to eight centimeters, but only blood was found.

The wound was packed and dressed as before, and the dressing was changed about every fourth day. The pain gradually disappeared, the pulse and temperature became normal, and one month after the operation the patient was discharged, apparently recovered, with a considerable diminution in the size of the liver. Two years later there had been no return of the abscess, and the patient was in fair health.

Case II.—This case is of especial interest on account of the unusually large size of the abscess.

C. M., a negro laborer, about forty-five years old, was admitted to the hospital for treatment in September, 1891. According to his account he had been suffering with acute hepatitis for about a year. There was no history of malaria or dysentery, but of irregular chills and fever, sometimes rigors, followed by fever and profuse sweats, pain in the region of the liver, progressive weakness, emaciation, and dyspnea.

The pulse ranged from 90 to 100, the temperature from 38.9° C. to 39.5°. On examination no tender spot, fluctuation, or bulging between the ribs could be detected. The lower extremities were much swollen, and the dyspnea was great. The abdomen was enormously distended, especially over the region of the diaphragm, from which it gradually tapered above and below—the patient's body having much the appearance of a barrel. The patient was chloroformed, and under aseptic precautions an exploratory incision into the abdominal cavity was made in the median line, just above the navel, and of sufficient length to permit the introduction of the hand, by means of which a large fluctuating tumor of the right lobe of the liver was distinguished,

almost filling up the abdominal cavity. Strong adhesions were detected on the right side, at about the level of the eighth rib, and an incision was made from without into the liver, through the site of the adhesions, between the eighth and ninth ribs, in the axillary line. This was followed by a jet of pus, which, owing to the tension under which it had been retained, escaped with such force that it struck the wall about five feet above the floor, and thus a good deal was lost before it could be made to flow into the vessel provided for it.

About six liters (one and one-half gallons) of pus were caught in a vessel, and it was judged that fully two liters escaped on the floor, making, by a conservative estimate, a total of eight liters. The wound in the median line was closed with catgut sutures, and healed by primary union, without suppuration. A large rubber drainage-tube was passed into the abscess-cavity through the opening between the ribs, and secured in that position by a safety-pin and adhesive plaster, with just enough projecting to allow the introduction of a small cork. This cork was for a time removed once daily to allow the pus to escape, later less frequently, and at the same time the tube was gradually withdrawn as the cavity contracted, until it was removed entirely two months after the operation. The patient was discharged, recovered, December 15, 1891. When last heard from, in June, 1893, through the kindness of Dr. Edwin Walker, who assisted me at the operation, the patient was in good health.

CASE III.—J. R., a negro boatman, twenty-one years old, was admitted to the hospital on December 21, 1891. He had been suffering with severe pains in the right side and shoulder for three or four weeks. No history of malaria or dysentery could be elicited. No chills occurred, but there was acceleration of pulse and elevation of temperature, with profuse perspiration. On account of the severity of the pain and its location, with the other symptoms, abscess of the liver, with adhesions, was suspected, and proved by getting pus on the introduction of a hypodermatic needle. The abscess was opened by an incision in the axillary line between the eighth and ninth ribs, about seventy-five cubic centimeters of pus being evacuated. The symptoms improved, but in less than a week the temperature began to rise again. Under chloroform-anesthesia a careful examination of the abscess-cavity was made, when the finger broke into a second abscess just below the first, about the same quantity of pus being evacuated. An opening was made between the ninth and tenth ribs and a tube introduced, so as to drain the lowest part of the cavity. The patient gradually improved, and was discharged, recovered, April 1, 1892.

RETENTION OF URINE FOR ELEVEN DAYS.

BY J. H. McCARTNEY, M.D.,
SURGEON P. M. CUSTOMS AND SURGEON IN CHARGE OF THE METHODIST EPISCOPAL HOSPITAL, CHUNGKING, CHINA.

THE patient, a Chinese married lady, about twenty-one years old, had given birth to a medium-sized child eleven days previously to my having been called, and up to that time had passed no urine, with the exception of a little dribbling now and again. There was a constant desire to urinate, but the woman could not relieve herself.

On examination we found the abdomen greatly distended, to all appearances like that of a woman before labor. The external genitals were in a normal condition, with the exception of the left labium, which was somewhat swollen. The woman complained of having great pain and high fever, but no rigors. She had eaten nothing for three or four days. As she was greatly frightened, an anesthetic was given and a catheter introduced. The urine came away with great force, nearly six and a half quarts in all (the exact amount is not known, as some was spilled in the beginning). It had a high odor and dark-brown color. The woman made an uneventful recovery. Dr. Gross says that death usually occurs in these cases in from three to four days from uremic poisoning.

MEDICAL PROGRESS.

Successful Trephining in a Case of Traumatic Hemorrhage into the Brain.—HARRIS (*Lancet*, No. 3693, p. 1444) has reported the case of a man, forty-three years old, who came under observation in an unconscious condition three days after having fallen down a flight of stairs while intoxicated. He could be roused and attempted to answer questions, but his speech was thick and quite unintelligible. A day after the accident he had a fit, although he had never had one before, and he became unconscious. On a level with and about half an inch to the left of the external occipital protuberance was an irregular, oblique scalp-wound about an inch and a half in length and extending down to the bone; there were also severe contusions of the right arm and left thigh. Shortly after coming under observation the man became drowsy and could not be roused to speak, although he resisted any attempt at passive movement of his limbs, excepting the left arm, which to all appearances was in a state of complete paralysis. The pupils were dilated and equal, and responded sluggishly to light. The eyes were slightly deviated to the right. During the night the man had eighteen fits. These commenced with twitchings at the left angle of the mouth and of the fingers of the left hand, and were characterized by stertorous breathing, foaming at the mouth, convulsions, chiefly confined to the left side, the eyes being strongly deviated to the right, and consciousness being entirely lost. There was incontinence of urine and feces. The temperature was 101.8°. On the following day, the fits still persisting, forty grains of potassium bromid and twenty grains of chloral were ordered. A fit occurred twenty minutes after the draught, at 10 P.M. another, and a third during the night. For the following ten days the patient remained in a drowsy condition, at one time relapsing into complete unconsciousness, at another being sufficiently sensible to attempt to answer questions when shouted to him, but his speech was never intelligible. His temperature varied between 101° and 103°. His respirations were occasionally rapid, at other times labored. On one occasion he had an attack of syncope. During the last two days of this period there was complete insensibility of the left conjunctiva and cornea, and no reflex could be elicited. No abnormality was discoverable with the ophthalmoscope. On the twentieth day after the accident the patient became much worse; he remained quite

unconscious, with labored respiration, and appeared comatose. It was finally decided to trephine over the center for the left arm, and the operation was accordingly undertaken on the twenty-second day after the accident. Ptosis of the right eyelid and left facial paralysis had made their appearance. After a segment of bone had been removed the dura mater was found to be of dark-purplish hue, but otherwise appeared healthy. An incision into the membrane was followed by a spurt of dark, venous-looking blood, which exploration showed to come from the center of a large clot, conical in form, its apex pointing toward the center of the brain; the outer layers were degenerated and buffy. The greater part of this was removed, and the cavity was well syringed out; a drainage-tube was introduced; the soft parts were brought together with a few sutures, and the wound was dressed antiseptically. Before the patient was removed from the operation-table the left corneal reflex was easily obtainable. There was some recurrent hemorrhage from the interior of the seat of the clot on the night of the operation. On the fifth and sixth days following it the patient had three fits very similar to those at the commencement of his illness, but there was no further recurrence. Otherwise recovery was uninterrupted. The return of power in the left arm was slow, but full use of the part was ultimately regained, and when dismissed the man was in all respects well.

A Case of Unilateral Gigantism has been reported by HORNSTEIN (*Virchow's Archiv*, cxxxiii, No. 3, p. 440; *Schmidt's Jahrbücher*, 1894, No. 8, p. 126), in which histologic examination (the first in cases of the kind published) disclosed a condition of hyperplasia of the soft parts, especially the connective tissue, the osseous tissue being similarly affected in slighter degree. The patient was a child, two and a half months old, the daughter of an insane mother, and the cause of whose death was not made clear by the autopsy. Both axilla contained a conglomeration of lymphangiectatic cysts as large as hazel-nuts, and adherent to the skin. The thymus could not be found. The face and trunk were symmetric. The right ear was the thicker, though not longer than the left. The upper and lower extremities on the right side were larger than on the left. Microscopically it was found that the increased size of the right ear was due to thickening of the skin and hyperplasia of the subcutaneous connective tissue. In the right foot there was also hyperplasia of the subcutaneous connective tissue. In the right foot there was also hyperplasia of the fatty and muscular tissues. Tendons, nerves, and vessels were also thicker upon the right side. There was but little increase in the size of the bones. The spinal cord and ganglia presented no abnormality. The peripheral nerves of the right side were thickened by increase in the epineurium and perineurium, and the nerve-bundles presented an increased diameter. On staining with hematoxylin some bundles appeared unduly pale, but on staining by the method of Weigert the medullary sheaths appeared normal. A small number of so-called bladder-cells, such as have been found in cases of cachexia thyreopriva or cretinism, collected in groups, and always cut transversely, were found only on the affected side. The possibility of any connection between the morbid condition and the thyroid gland is emphatically rejected. The muscle-buds of Kölliker were enlarged, and richly developed on the affected but not on the sound side.

An Unusual Mode of Transmission of Syphilis.—SENGER (*Dermatologische Zeitschr.*, 1894, Band i, Heft 5; *Monatssch. f. prakt. Dermatologie*, Band xix, No. 4, p. 211) has reported the case of a man, thirty-five years old, who was infected with syphilis at the age of twenty-eight, presenting a chancre, then enlargement of the inguinal glands, and later mucous patches in the pharynx. He submitted to an energetic course of treatment with mercurial inunctions, but eight weeks afterward patches reappeared in the pharynx, the glands of the neck became enlarged, and a syphilitic palmar psoriasis made its appearance. The man submitted to a second energetic course of treatment with mercurial inunctions, which was followed by a long course of potassium iodid. After this there were no further symptoms of syphilis. Nevertheless, the patient a year later underwent another course of inunctions, and afterward married a healthy girl, who gave birth to three healthy children, without any miscarriages. The woman came under observation subsequently with several typical broad condylomata upon either side of the labia majora, slightly enlarged glands in the groin, and syphilitic psoriatic spots upon the neck. On inquiry it was learned that the husband had several months before observed upon the penis an herpetic ulcer that caused no pain and soon disappeared. It was from this time that the symptoms of the wife dated. There was no evidence that the husband had received a new infection, or that the wife had been exposed to any other source of infection. The explanation offered is that somewhere in the body of the husband—perhaps encapsulated within the prepuce—the syphilitic poison had remained latent, until set free by some unknown or indifferent cause, when it occasioned the vesicle which proved capable of transmitting the infection.

Congenital Absence of the Pectoralis Major and Minor Muscles of one Side.—LITTLEWOOD (*Lancet*, No. 3697, p. 19) has reported the case of a boy, ten years old, who, following a slight injury to the right shoulder, discovered that he had no armpit on the corresponding side. At the front of the chest, on the right side, all the ribs were visible, being subcutaneous and uncovered by muscle. Neither pectoralis major nor minor could be seen or felt. The coracoid process stood out distinctly. A firm membrane was attached to the inner extremity of the first rib and adjacent portion of the clavicle at one end, and to the inner part of the tip of the coracoid process at the other end. It became tense on drawing the arm to the side, and probably represented the costo-coracoid membrane. In this position of the arm there was also to be felt a slight ridge of the skin, like a strand of fascia, about the position of and corresponding to the anterior axillary fold. The other muscles about the scapulo-humeral articulation were much better developed upon the left side, and this was more noticeable in the anterior portion of the deltoid and coraco-brachialis muscles. The nipple was present and well developed. The shoulder-joint was powerful, and all of the movements were well performed. Circumduction was much more free than on the left side.

THE RESPONSIBILITY OF THE INSANE.

THE never-failing topic in medical jurisprudence, of the responsibility of the insane, was made the subject of special discussion in the Section on Psychology of the British Medical Association at its recent meeting. On the principle that misery loves company, we may find some satisfaction in learning that English alienists are as much troubled by antiquated methods of legal procedure as psychologists are in this country. The law, being so largely based on precedent, pursues in some respects a system diametrically opposed to scientific principles. In a general way, we may say that in science the most recent authoritative utterance is assumed to be the most trustworthy, but in law the antiquity of a maxim is a point in its favor.

In 1843 a formal declaration was made by English judges as to the rule upon which the plea of insanity is to be accepted as a defense for homicide, and this still stands, though some judges, appreciating the advances in science, have widened the application so that it is less oppressive. Nevertheless, when it is considered that the rule was laid down fifty years ago—even then, doubtless, not representing fully the medical knowledge of the time—and that in the period that has elapsed greater progress in criminology has been made than in the two centuries preceding, we can realize how great is the discordance between the practice of courts and the views of experts.

Though judges and juries, both in this country and in England, occasionally take a scientific view of the responsibility of the insane murderer, the usual practice is to look upon the plea of insanity as a mere expedient of the defence. The sentiment of the community is largely in the same direction, and is of course likely to influence juries, and not be entirely without influence upon judges and prosecuting officers. There are several reasons for this tendency in public opinion. Every large community presents almost every grade of mind, from the most exact to that which is the subject of the wildest vagaries. It is often difficult, and sometimes impossible, to determine when reason ceases and insanity begins. The whole question is most abstruse, and hence, as in all abstruse questions, ignorant persons do not hesitate to form and hold opinions. That the readiness of some professional experts to exhibit a partisan interest on the side for which they are called has materially discredited expert testimony is well known. Prosecuting attorneys, judges, and the community at large, are wont to regard the statements of medical witnesses for the defence as dictated by fees rather than by belief.

Another circumstance that prevents calm consideration of the evidence of irresponsible insanity is that murders committed by such irresponsibles are often atrocious, and the feelings of the community are highly wrought. The horrors of the murder are detailed with great vividness by the daily newspapers, and prosecuting attorneys are held responsible for the swift expiation of the crime.

The delusional insane are so erratic and impulsive that persons having no relation to the delusions may be murdered in a sudden burst of passion over a trifling dispute. In a well-known Philadelphia case a tradesman was killed during a disagreement as to the merits of an article that had just been sold. On the trial it was shown that the prisoner had for years exhibited the typical conditions of delusional insanity, yet the trial-judge would not allow the question of the man's mental condition to be decided apart from the trial proper. The prosecuting attorney pressed for and obtained a verdict of murder in the first degree, offering no expert testimony to combat that produced by the defence. Nevertheless, the error of the verdict is doubtless admitted, for several years have elapsed since the trial, and the

death-warrant is not yet signed. In a similar case in Washington, however, the judge charged the jury in accordance with the views of the experts, a verdict of not guilty was rendered and the prisoner was sent to an asylum.

It will be seen from these cases that the absence of sound scientific basis for the present attitude of the law gives rise to uncertainty of judgment, and leaves the fate of a murderer almost to chance. This defect is fully brought out in the British discussion, and cases are noted parallel to those just cited. In the Philadelphia case, the policeman who arrested the murderer and the magistrate who committed him were allowed to testify that they did not consider him insane, and English jurisprudence parallels this in the remark of LORD WESTBURY "that any ordinary man is as good a judge of insanity as anyone else."

In considering this topic we must carefully distinguish between the abstract question of moral responsibility and the concrete one of actual disposal of a particular case. Alienists are not contending for the release of the criminal insane; they are simply contending for a clear judgment of each case upon scientific principles. If it be the will of a community that anyone who is known to have deliberately killed another shall die, so let it be; but such is not the will of any civilized community. All recognize conditions of irresponsibility that render punishment out of the question, and it is the purpose of the law, assisted by science, to ascertain the existence of such mental conditions in any given case. The medical man who honestly advocates a particular opinion (and with the mere fee-taker we have no concern) arrives at his views as he would at any other diagnosis, by a consideration of the phenomena of the case. He decides that a prisoner is insane, as he would decide that he had typhoid fever or pulmonary tuberculosis. With the effect of that decision on the subsequent course of the law the expert has nothing to do. It is obvious that an irresponsible murderous lunatic ought not to be at large, but the necessary commitment to an asylum is to be provided for by act of legislature and enforced by the court.

The discussion before the British Medical Association seems to have been limited to papers prepared for the occasion. DR. MERCIER recommended that the law should be altered so as to allow a verdict of "guilty, but insane." SIR FREDERICK BATEMAN discussed the topic of "Criminal Anthropology," and expressed doubts as to the soundness of the position of the Italian school. The Section resolved to solicit Parliamentary action. The tendency of American lawyers to follow English precedent will render it likely that if advanced methods of determining and affirming the insanity of criminals be attained in England it will not be long before the reform will influence American jurisprudence.

A peculiar feature is exhibited in the report of the meeting as published in the *British Medical Journal*. We give it *verbatim*:

"The ruling of MR. JUSTICE CAVE in the case of BROCKLEHURST was even more emphatically contradictory of the literal interpretations of other judges. When counsel for the prosecution was about to address the jury on the subject of the prisoner's insanity the judge interposed with the remark that the doctor had said distinctly that the prisoner was of unsound mind. Counsel suggested that the question for the jury was whether the prisoner was capable of appreciating the difference between right and wrong. The judge said, 'No; the question is whether he was insane at the time—(laughter)—and if a man is suffering from the delusion that his wife tries to poison him and is unfaithful to him, and attacks her in consequence, it is as clear as anything can be that the man is mad.' Turning to the jury he said, 'Do you feel any difficulty about it, gentlemen?' 'Not the slightest,' said the foreman. (Loud laughter.)"

It is often said by sarcastic Americans that the sense of humor must be highly developed in our British cousins to permit them to extract amusement from the pages of their comic weeklies. It is not quite clear from the report whether the laughter was in the court or at the meeting, but it must require a high sense of humor to perceive anything laughter-provoking about the incident, either in its occurrence or in its relation.

REVIEWS.

A TREATISE ON APPENDICITIS. By GEO. R. FOWLER, M.D., Examiner in Surgery, Medical Examining Board of the Regents of the University of the State of New York; Surgeon to St. Mary's Hospital and to the Methodist Episcopal Hospital; Consulting Surgeon to the Relief Hospital and to the Norwegian Hospital, Brooklyn. 8vo, pp. 190, with 35 woodcuts and 4 plates. Philadelphia: J. B. Lippincott Co., 1894.

IN this book we have a revised reprint of the widely commended series of articles by Dr. Fowler, which appeared in the *Annals of Surgery* last spring. The work is systematic, scientific, and complete in so far as the very latest knowledge of the subject can make it. An unusual practical experience with appendicitis, together with a just appreciation of the work of others and a familiarity with the literature has enabled the author to present a most satisfactory and valuable monograph

which can without reserve be heartily commended. A wide circulation of the volume must certainly lead to earlier diagnosis of this terrible disease, and to a much lessened death-rate if the details of treatment set forth are adhered to.

Full chapters are devoted to anatomy, clinical history, etiology, bacteriology, pathologic anatomy (written by Dr. Van Cott), diagnosis, and treatment. In all of these will be found many original observations and ideas, as well as numbers of hitherto but little known or little appreciated facts. The chapters devoted to bacteriology and pathologic anatomy are of especial note and interest, and demonstrate how quickly the innumerable workers in these fields now work out conclusions. The illustrations are numerous and well executed, while typographically the work is of high grade.

MATERIA MEDICA, PHARMACY, PHARMACOLOGY, AND THERAPEUTICS. By W. HALE WHITE, M.D., F.R.C.P. Professor and Lecturer on Materia Medica and Therapeutics, etc. Edited by REYNOLD W. WILCOX, M.A., LL.D., Professor of Clinical Medicine and Therapeutics at the New York Post-Graduate Medical School and Hospital, etc. Second American Edition revised. 8vo, pp. 661. Philadelphia: P. Blakiston, Son & Co., 1894.

BOTH author and editor of this book have done their work so well that it seems ungracious to inquire whether the work was worth doing. Yet we doubt very much if the very brief discussions of the physiologic action and therapeutic effects and uses of many of the drugs mentioned in this book will be of service either to student or physician, unless he has at the same time access to a larger work, such as Brunton's or Bartholow's; for therapeutics is not a subject that readily lends itself to condensation. Unless one is satisfied with the merest empiricism, no concise manual of therapeutics can, therefore, stand by itself as a safe guide to the choice of remedies. As a note-book to refresh the memory of the student and as a quick reference-book for the experienced physician, who merely wishes a concise statement of some certain point, the book is admirable. Evidently no pains have been spared to make it accurate, and its arrangement is scientific. It is the best book of its class now in the market, and it has been made so in no slight degree by the additions and emendations of the American editor.

VITAL STATISTICS OF NEW YORK CITY AND BROOKLYN. Covering a Period of Six Years ending May 31, 1890. By JOHN S. BILLINGS, M.D., Surgeon United States Army, Expert Special Agent. Quarto; pp. 529 and maps. Washington, D. C.: Government Printing-Office, 1894.

THIS is a handsome volume, containing tables and illustrations prepared under the direction of Mr. William A. King from data furnished by Mr. D. L. N. Peixotto and others. The data are grouped in two periods, the six-year period and the census-year period, each ending May 31, 1890. The maps are most instructive and show two principal points. The first is that the death-rate, without regard to the class of inhabitants, is greater in both cities over made land and reclaimed swamps and bays than elsewhere; and second, the death-rate is highest in the most crowded tenement-districts. Perhaps the general reader will be interested to note the fact that the death-rate among the children of Irish mothers is highest, and it is lowest for the children of mothers born in Russia and Poland. The statistics are given in extreme detail and furnish material for a study too extended for the space at our disposal. This is one of the most valuable statistical works published during the past year, and should be studied in connection with the report of the Bureau of Labor in relation to the slums of great cities. It should also be studied in connection with the condition of the labor-market during the six years which it covers.

GUY'S HOSPITAL REPORTS. Edited by W. A. WHITE, M.D., and W. H. A. JACOBSON, M.A., M.Ch. Vol. L, being Vol. XXXV of the third series. London: 1894.

IN addition to the many admirable monographs and reports contained in this volume, there is an index from Vol. I, 1836, to Vol. L, 1893, which will be very much appreciated by authors and students. A study of five cases of pernicious anemia with determinations of the iron in the viscera, and some observations on the urine are contributed by F. Gowland Hopkins, Gull Research Student. The liver and spleen in all cases contained an excess of iron, though the amount varied widely in the different cases. The urine was highly acid, nearly always dark in color, and the absorption-band at F could almost always be observed spectroscopically, even when the color was less marked than usual. The specific gravity varied between 1010 and 1012, and uric acid crystals were frequently deposited, even when the percentage of uric acid was normal. The pigments were normal urobilin and hematoporphyrin.

The report of one hundred and forty cases of pyrexia by Dr. J. H. Bryant is an extremely valuable research, and the same may be said of Perry and Shaw's paper on "Diseases of the Duodenum." Hale White contributes a clinical study on the effect of giving levulose and inulin to patients suffering from diabetes mellitus, confirming what has heretofore been published on this topic.

CORRESPONDENCE.

HYDROPHOBIA—STATISTICS DESIRED.

To the Editor of THE MEDICAL NEWS,

SIR: Will you permit me through your columns to ask that my professional brethren will communicate to me the occurrence of cases of so-called hydrophobia in their practice for the year 1894, from January 1st, and so on until the end of this year?

I would like in all cases to learn: 1. The sex and age of patient; *a*, the kind of animal that is credited with the inoculation; *b*, its state of health; *c*, the provocation to bite (if any existed). 3. The reasons why the animal was (if it was) deemed rabid. 3. The seat of the bite (or other mode of inoculation). 4. The fact and method of cauterization (if any). 5. The time between the inoculation and the outbreak. 6. The symptoms of the

outbreak—the occurrence of mania or imitation of dog actions. 7. The remedies used, and doses, with their seeming effect. 8. The issue of the case, and when death occurred. 9. The investigations made to exclude the presence of disease other than so-called hydrophobia. 10. The findings on autopsy—if one was held.

I shall, of course, acknowledge in future publications aid received in continuing my studies in regard to this subject. Yours respectfully,

Charles W. Dulles.

4101 Walnut Street, Philadelphia.

NEWS ITEMS.

Death of Helmholtz.—The distinguished physicist Professor Hermann von Helmholtz, of Berlin, died on September 8th, at the age of seventy-three. Professor Helmholtz was born August 31, 1821, at Potsdam, and received the degree of M.D. in 1842. In 1847 he read the epoch-making paper on "The Conservation of Force," before the Physical Society of Berlin, at which time he was not aware that Mayer, in 1842, had first advocated essentially the same truth. In 1849 he was appointed Extraordinary Professor of Physiology at Königsberg, and in 1855 he became Professor of Physiology at Bonn, and in 1858 he was called to Heidelberg. In 1871 he was made Professor of Physics in the University of Berlin. In 1891 he was made President and Director of the Physikalisch-Technische Reichsanstalt. The scientific work of this great man was, much of it, connected with medicine, so that physicians are well aware how great is the debt we owe him. Ophthalmologists especially can never forget the inventor of the ophthalmoscope and the writer of the *Manual of Physiological Optics*. There is no department of medical science that, directly or indirectly, was not enriched by the long life of noble labor of this brilliant and masterly mind.

A New Surgical Work.—*A System of Surgery*, edited by Frederic S. Dennis, M.D., and John S. Billings, M.D., is announced by Lea Brothers & Co. as shortly to appear, in three imperial octavo volumes. The list of contributors embraces such names as W. T. Bull, Charles McBurney, and Robert F. Weir, of New York; Councilman, Porter, Richardson, and Warren, of Harvard; Carmalt, of Yale; Keen, White, Roberts, and Wharton, of Philadelphia; Welch, of Baltimore; Park, of Buffalo; Conner, of Cincinnati; Mudd, of St. Louis; and Senn, of Chicago.

Prof. Rollett, of Lyons, Professor of Hygiene, and a well-known syphilographer, died August 2d, at the age sixty-nine years. He contributed freely to the literature of venereal diseases.

A. B. Miles, Professor of Surgery in Tulane University, New Orleans, died August 5th, at the age of forty-one years.

A Statue to Claude Bernard will be unveiled at Lyons on October 26th.

THE RATIO THAT ALIMENTATION SHOULD BEAR TO OXYGENATION IN DISEASE OF THE LUNGS.[1]

BY BOARDMAN REED, M.D.,
OF ATLANTIC CITY, N. J.

WITHIN the past two decades much has been heard of super-alimentation and forced feeding in pulmonary tuberculosis. It seems to have been assumed in many quarters that the more food a tuberculous patient can be made to take, the better his chances of recovery. Recent studies and observations have, however, led me to consider seriously whether it is not just as true in diseases of the lungs as it admittedly is in other diseases, that excess of food beyond the amount that can be perfectly digested and assimilated is injurious. It seems even probable that in pulmonary affections the gaseous products of indigestion and imperfect oxidation, being partly excreted by the lungs, may be more deleterious than in other cases.

The title of this paper assumes that there exists a definite ratio between the amount of oxygen that a pulmonary patient takes in and the amount of food that he is capable of digesting and assimilating. When the intake of oxygen is large, as occurs in the case of robust persons who are exercising actively in the open air, it is manifest that a maximum amount of food will be demanded and can be safely given. When, on the other hand, a patient has one or even both lungs crippled by disease, leaving him, as often happens, only one-half or one-third his normal breathing-power, and is moreover entirely at rest, being confined to bed in a close, ill-ventilated room, his consumption of oxygen is relatively very small, and the amount of food that he can digest and thoroughly oxidize into a nutritive pabulum for the uses of the economy is very much less.

Between these two extremes are found patients with all possible degrees of capacity and opportunity for absorbing oxygen, and, in consequence, with equally varying degrees of capacity for digesting and assimilating food. If the bedridden patient with only one lung be compelled to ingest even one-half as much food as is imperatively required by the robust outdoor laborer, mischief must result from the surplus that cannot be oxidized into assimilable forms, even if it were possible for it to be digested. Evidently, then, there is such a ratio as has been assumed, and it is exceedingly important that this fact be borne in mind in deciding as to the proper feeding of any case of pulmonary disease.

My attention has of late been particularly directed toward the study of diet and digestion, and, meeting often with such surprisingly good results from carefully-selected and occasionally even severely-restricted diet in numerous forms of disease, it occurred to me last winter to ascertain what a more careful diet, in connection with a larger allowance of oxygen in the form of pure air, could do for my tuberculous patients. About the time when this resolve was made there came into my hands several new cases of pulmonary tuberculosis, including one in which, on account of the extreme irritability of the stomach, full feeding was out of the question. Following will be found a report of it:

CASE I.—The driver of an express-wagon, thirty years old, was first seen by me January 19, 1894. He had always been strong until some time in August, 1893, when he began to cough severely and to have shortness of breath. He first noticed that he had fever about the first of October, and took to his bed early in November on account of fever and debility. He had previously vomited a good deal, often as much as five times a day. He had remained in bed from the time mentioned till he came under my care. While in bed he had been vomiting several times daily, and particularly after almost every meal. His previous medical attendant was said to have urged very liberal feeding—that the patient be made to take as much as he possibly could. I found the man with a temperature ranging from 101° to 102° in the afternoons and with a pulse usually much above 100. When he had last been able to get out, nearly two months before, he had weighed 112 pounds. I should have estimated his weight at somewhat less at the time of my first visit—probably about 105 pounds. He was then expectorating an abundance of the usual nummular sputum of pulmonary tuberculosis in the second stage, and said that he had been doing so for several weeks. He was having copious night-sweats, and his nights were further disturbed by a frequent harassing cough.

Examination disclosed dulness on percussion at the right apex anteriorly, and a similar condition somewhat less marked posteriorly; increased vocal fremitus and subcrepitant râles over the same regions, with some gurgling râles and cavernous breathing

[1] Read before the American Climatological Association, in the Congress of Physicians and Surgeons, Washington, D. C., May 29, 1894.

at a point in front a short distance below the clavicle. At the left apex anteriorly there were the usual signs of a slight infiltration.

The man lay in bed, heavily covered, in a close, warm room of very small dimensions and without any ventilation except such as was afforded by a door opening upon a staircase which led to the living-rooms below. The directions now given were that the windows in the room should be opened to the fullest extent possible and kept so constantly during the day, except in very bad weather, and that they should be open at least six inches at night; the patient meanwhile to be covered just sufficiently to be comfortable. To prevent his "taking cold" and to improve his nervous tone, he was to be sponged at first with cool and later on with cold water, every morning. He was allowed small portions of the blandest liquid diet at intervals of two hours, and tablets containing one-tenth of a drop of creosote were administered, one every two hours, to stop the vomiting and improve digestion.

The vomiting ceased at once, and never recurred except once some ten days later as a result of imprudent eating in violation of express rules. After the stomach had regained its tone and the appetite had become voracious, as it did without other medicine, from the effects of the spongings and freer ventilation, I was obliged to impose stringent restrictions to prevent over-eating.

The man was allowed a plain breakfast of beefsteak or chops and bread and butter, preceded an hour before by a glass of hot water in which was dissolved a little table-salt. In the middle of the day he was directed to take, instead of his accustomed hearty dinner, merely a light lunch of crackers or stale bread and butter, with a baked apple or other fresh fruit, such as grapes or oranges. His supper was much the same as his breakfast, except that either roast or broiled meat or fowl was permitted, with one or two vegetables, but no desserts except fresh fruits. Milk was also permitted.

Pari passu with the gain in gastric tone there was an improvement in the cough, fever, and most of the other symptoms. By the end of two weeks the temperature had ceased to rise above 99.5° in the afternoon; the night-sweats had nearly disappeared and there was no longer any sputum, though still a dry cough. The physical signs showed corresponding improvement. The pulse continued to be weak and rather rapid, and attempts to strengthen it by administering a glycerite of the hypophosphites (Churchill's formula) disturbed his digestion somewhat, and so was abandoned. Minute doses of arsenic iodid were then given with good effect, and at times small doses of creosote were again administered. From the beginning the chest was painted over the affected areas with tincture of iodin every day till the skin became sore; then it was left a few days until new skin formed, when the painting was resumed, and so on.

The man continued to improve in all ways until, at the end of a month from the time the treatment began, he was able to drive out every pleasant day, and was required to sit out or lie on a cot in the front of his house in all weathers except the roughest. Fortunately the winters in Atlantic City are usually very open and mild, the past winter having been exceptionally so, and therefore this patient enjoyed a continual out-door air-bath from morning until night almost every day. By this time his weight had increased to 126 pounds, and there was no longer any elevation of temperature, except that it occasionally reached 99° at night.

On February 27 the patient began to suffer from a relapse, which I attributed to a lapse on his part from the stringent dietetic rules that had been imposed on him. He had gone back to his former habit of eating a heavy mid-day dinner, in addition to two other hearty meals. *Post hoc*, whether *propter hoc* or not, he began to cough and raise sputum, and for several days his temperature again rose above 100° in the late afternoon, while physical examination revealed moist râles below the right apex. A return to his former strict diet was followed by a prompt improvement again, which progressed thereafter uninterruptedly.

By May 2 the patient had recovered his former appearance of robust health, and weighed 132 pounds. He has been at work since early in April. On the date mentioned he was presented at a meeting of the Atlantic County Medical Society, and examined by a number of members. At this time there was still some dulness below the right apex, with a rather harsh respiratory murmur, but no râles whatever. He reported that he had not coughed at all for three or four weeks and that he felt as well as he had ever done.

The foregoing case has seemed sufficiently important to be reported in detail, on account of the very prompt and striking effects that resulted from giving the man more air and less food than he had been receiving before. The report also embodies substantially the method of treatment, both hygienic and medicinal, that has been followed in numerous other cases of pulmonary disease which have been under my care during the past winter and spring. Reports of these are here appended:

Case II.—A widow, forty years old, a resident of Philadelphia, and sojourning in Atlantic City for her health, was said to have had peritonitis in March, 1893, and since then to have taken morphin—her dose, when she came under my care, having been about one grain daily, hypodermatically, with a proportionate amount of atropin. She had been coughing more or less for upward of a year, and badly for about a month, after an acute attack in Philadelphia of what was considered to be congestion of the lungs threatening pneumonia. She was very thin and emaciated and exceedingly nervous. She was supposed to have had at one time spinal meningitis—probably aggravated spinal irritation. Her temperature at the time of my first visit, December 27, 1893, was 99.6° at 11.00 A.M., and subsequently ranged from 100° to 102° in the late afternoon. She had sweats at night, until they were controlled by a pill of agaricin, gr. $\frac{1}{12}$, with Dover's powder, gr. 1, one or two of which were given at

bedtime. She coughed hard, especially at night, raising a moderate amount of characteristic tuberculous sputum, and occasionally vomited after eating, though with nothing like the frequency in Case I. Examination disclosed the usual signs of a small area of consolidation at the left apex, with a larger area at the right, which had begun to soften. The treatment adopted was similar in the main to that described in Case I. Morphin was gradually withdrawn, codein with nerve-tonics being substituted, and later the codein itself was withdrawn. Similar rules of diet were made as in the previous case, but could not be carried out so strictly, as the patient lived in a boarding-house in which dinner was served in the middle of the day, and the *menu* at supper afforded a scanty variety. Sweets were forbidden and moderation enjoined as to starchy articles. The net result was that the patient took considerably less food than before, and in consequence digested it much more perfectly. She had a fairly good stomach after she began to improve, and creosote was given her in doses of from one to three drops after eating.

On January 5 there was a slight hemoptysis which was promptly controlled. By January 20 my notes show that her temperature no longer rose above 99.5° in the afternoon, and the cough had ceased entirely, not having troubled her at all for the week previous. All narcotics were now discontinued.

On January 27 there was a return of fever, the temperature rising to 101°, but without any return of the cough or expectoration. The patient had been disregarding her rules of diet and indulging in some indigestible food. Within a few days, the patient meanwhile having been kept in a recumbent position, the fever disappeared and the temperature for sometime afterward did not rise above 99°.

In this case the early and apparently entire cessation of the cough was very noteworthy, but the dulness on percussion remained, with some harshness of the respiratory murmur. Some slight moist sounds persisted long after the patient insisted that she no longer coughed or raised anything, but by the end of two months dulness and some increased vocal fremitus were the only noticeable signs over the affected areas. She had gained five pounds in weight and was less nervous.

The patient left Atlantic City for the interior of Pennsylvania on May 1, and during four or five days preceding that date she had complained of a slight cough for the first time in three months, and had occasionally raised a little sputum in the morning. The temperature remained normal, but a few faint râles were found to have reappeared at the right apex. On May 18 a letter was received from her stating that she had developed whooping-cough of a severe type, and with this was again having fever and night-sweats, so that a serious relapse of the tuberculous trouble has evidently taken place as a result probably of the pertussis, which possibly caused the slight return of cough in the last days of April.

Case III.—A lady, twenty-five years old, a member of a family in which there has been much tuberculosis, had always been accustomed to plain living, but last summer gave up housekeeping and boarded in a house in which the table was rather luxurious. Her digestion became somewhat impaired, and about midsummer she began complaining of a stubborn dry cough. The usual remedies had no effect, and in December last I found slight but well-marked infiltration at both apices. Her diet was restricted, though less than in the preceding two cases, as her habits were active, and the same regimen was enjoined. The cold sponge-baths and constant counter-irritation by means of iodin were particularly insisted on, and the patient, having been somewhat of a bicyclist in former years, was urged to resume that form of exercise, and keep out of doors on her wheel as much of the time as possible. She was directed to take continually creosote in doses of from one to three drops on sugar after each meal. She shortly after began to show improvement, and with but few interruptions progressed favorably until this writing, May 18. She now weighs six pounds more than at the time of beginning treatment, and no longer coughs. Her temperature, which was rising pretty regularly to 99.5°, and sometimes to 100° in the latter part of the day, has for some time not gone above normal. The physical signs indicate an arrest of the disease at both apices.

Case IV.—A widow, twenty-nine years old, whose husband died two years ago of pulmonary tuberculosis complicated with alcoholic gastritis, had always had good digestion, and has been fond of sweets, including candies, and not over-digestible lunches beween meals. She had had a hacking cough since the time of her husband's death, and was greatly emaciated, her weight ranging between eighty and ninety pounds. A year ago, after an attack of influenza, she began to expectorate. She came under my care in February last, and I then found a small consolidated portion of lung below the right apex, as plainly shown by signs recognizable both in front and behind. There were also numerous subcrepitant râles in the same region. She had been seen by Dr. R. G. Curtin, in Philadelphia, some months before, and he had prescribed guaiacol. Her former medical attendant had continued this drug, giving no other medicine. I also directed that the guaiacol be continued in doses of from two to three drops after meals, and placed her at the same time upon a somewhat restricted diet, forbidding especially all lunches between the three regular meals, except that milk was allowed at bedtime, and cutting off rigidly all indigestible dishes.

Constant counter-irritation over the affected spot was ordered, and the patient was strictly enjoined to spend a large part of every day out of doors, except in the worst weather, and to have ample ventilation of her room at night. The clinical thermometer, the regular use of which I always insist upon in all cases of suspected tuberculosis, disclosed

slight rises of temperature for some time after the patient came under my care, never, however, going above 100°, and within a few weeks after the institution of the hygienic measures just described it ceased to rise above 99°. The expectoration also gradually diminished. At the time of my last examination, May 14, there was still dulness at the right apex, both in front and behind, with slightly increased vocal fremitus and wavy respiration, but no râles of any kind, and the patient reported that she had neither coughed nor expectorated for three or four weeks. Her weight had increased to ninety-two pounds, which is above her average for the past six years.

I consider the disease arrested in this case, but the patient is continuing the guaiacol with the still more important hygienic precautions. She now eats all that her appetite demands at the three meals, but takes no lunches except the milk at bedtime.

Case V.—A shopkeeper, sixty-two years old, of very broad chest and robust build, weighed 220 pounds shortly before he became ill. I was called to see him on January 18, 1894, on account of a moderate hemoptysis. He had been coughing somewhat for six months or more. A small area of dulness was found a few inches below the right apex, anteriorly, and there was feeble respiration over the same region. The bleeding yielded rather slowly to treatment, and was followed by a rise in the temperature, which reached 101° at night, falling to the normal again in the morning. There began to be raised a considerable amount of sputum, which continued to be blood-streaked for a week or more. The cough became very severe, especially at night. The patient had also long suffered from intestinal indigestion, with flatulence and constipation. He was ordered a plain but substantial meal, mainly of meat, eggs, or milk, morning and night, with a light lunch in the middle of the day; also a full pint of hot water an hour before each meal, with a view to overcoming his constipation and lessening his obesity. His chest was sponged with cold water every day, and the skin over the affected region was kept sore with iodin. Creosote was given in small doses after each meal, and on account of the unusually severe character of the cough, which prevented sleep and threatened further hemorrhage, an anodyne mixture had to be administered at night. A slight recurrence of hemoptysis at the end of a week complicated matters, but after this marked improvement set in. The temperature speedily fell to normal, cough and expectoration steadily lessened, and, what most delighted the patient, his constipation and intestinal flatulence were overcome, while his protuberant abdomen sensibly retracted. For nearly a month this improvement continued, and the patient seemed to be getting well, when he contracted a severe "cold" by standing on a street-corner engaged in conversation, after a long walk, on a cold day in March, and the congestion thus set up resulted in another hemorrhage.

From this time on hemorrhages recurred every week or two, in spite of a plentiful use of the best astringents. The infiltration finally involved the greater part of the right lung and invaded also the apex of the left. A cavity has formed in the center of the right lung, and the case is likely now to follow the usual course. After the hemorrhage began to recur with such alarming frequency the hygienic method was virtually abandoned; efforts were made to restrain the violence of the cough at all hazards, and anodyne cough-medicines had to be resorted to freely, regardless of the effect on digestion. Moreover, the family had an invincible dread of fresh air, so that all attempts to carry out the plan of securing a freer oxygenation of the blood were nullified.

Case VI.—A physician, thirty-six years old, had infiltration below the apex of the right lung when a medical student in Philadelphia in 1879, according to the diagnosis of Prof. J. M. Da Costa. He had fever and cough during most of the following winter, and had to abandon his studies for some time. The disease was later controlled, and he regained good health. In October, 1893, having meanwhile moved to Atlantic City, he again developed cough, with a return of the signs of consolidation of the right lung. His temperature was a little above normal nearly every afternoon until about the 1st of January, 1894, and occasionally, though rarely, reached 101°. He treated himself for the most part, but occasionally consulted me during the months of December and January. He has always had a perfect digestion and made no change in his usual full diet—three regular meals daily, with dinner at night—except that a generous allowance of milk was now substituted in part for other less nourishing foods. He continued in full practice and was riding out of doors in an open buggy during the greater part of every day, and much of the time during the evening. Vigorous counter-irritation was kept up over the affected spot, and creosote was taken to the extent of about fifteen drops daily.

Various tonics, including cod-liver oil, arsenic, and strychnin, were taken at different times. In short, the treatment was counter-irritant, antiseptic, and roborant to the fullest extent, and, what was doubtless most important of all, oxygenation was maintained at the maximum point possible without over-fatigue, by almost continual driving out of doors in a pure air. By the middle of December the signs, as well as the symptoms, indicated a rapid arrest of the disease. The patient's weight at the beginning of the attack had fallen to 158 pounds; it is now 186 pounds. Some dulness persists over the area formerly affected, but otherwise the patient is well. He has had no expectoration and no cough whatever for nearly three months.

In Case V a specimen of the sputum obtained at an early stage of the disease, when the cough and expectoration had almost ceased, was examined microscopically by Dr. D. Braden Kyle, of Philadelphia, and a few bacilli found. No examination of the sputum was made in the other cases, as the physical signs and symptoms were decisive and left

no room for doubt as to the character of the malady in any of them.

The foregoing do not represent selected cases, but include all the cases of undoubted pulmonary tuberculosis that have been under my care for any considerable time during the past winter and spring. One serious case in the third stage which was sent by Dr. Ralph Walsh, of Washington, D. C., remained about two weeks only, as, though some little improvement occurred in appetite and digestion from the change of climate, I was unable to promise any lasting gain from a longer sojourn. A number of others in the early stages, in the persons of transient visitors, were seen a few times, most of them at my office, and, as a rule, there was more or less amelioration of the symptoms, but none of these were under methodical treatment.

The results in the six cases here described were, on the average, considerably better than I have been accustomed to see in former years, when it was not my practice to impose any restrictions upon the diet of tuberculous patients, but rather to encourage the fullest feeding possible. Neither in my experience in Atlantic City during many years previously to the past winter, nor in Thomasville, Ga., during the winter of 1892–93, where I saw a large number of cases of tuberculosis in all stages, were the fever, cough, general nutrition and body-weight found so generally to improve under any of the methods of treatment then employed. These later results have been obtained in four out of the six cases, with the aid of so little internal medicine, and that little addressed almost entirely to the digestive tract, that the conclusion seems irresistible that the management of the diet and hygienic regimen generally should receive the chief credit. The other two cases, V and VI, are the exceptions that prove the rule. Case V had a rather poor digestion and the anodyne and astringent mixtures apparently necessitated by his cough and recurring hemorrhages exerted, without doubt, an injurious influence upon his digestive organs.

Case VI had a stomach that could digest anything, and, therefore, this patient could bear and progress favorably under a more active medication than most others.

It is doubtful whether any drugs yet discovered have a directly curative effect on tuberculous lesions, though there may be a few, including some of the preparations of the hypophosphites, that, by stimulating the circulation of blood in the lungs, aid in improving the nutrition of the diseased tissues. It is probable that the majority of drugs, as well as those changes of climate that seem to exert a favorable influence in pulmonary cases, effect their good results for the most part indirectly by increasing appetite, improving digestion, and stimulating the vital processes generally, thus increasing the quantity and bettering the quality of the blood that reaches the diseased structures. Indeed, we are justified now in believing that an abundance of pure healthy blood, circulating normally in the lungs, is the most essential prerequisite to a cure of pulmonary tuberculosis. Hence the paramount importance of looking closely to the blood-making processes by securing as perfect digestion as possible, together with a complete oxidation of its products, so as to spare the lungs from the injurious task of assisting in the excretion of the poisonous compounds resulting from suboxidation and decomposition. To attain these ends satisfactorily, the total amount of aliment ingested must not be in excess relatively to the amount of oxygen absorbed.

We may, therefore, safely insist upon liberal feeding whenever the patient can exercise freely out of doors in any clean aseptic air.

When, on account of fever, rest of the body is temporarily necessary, a fairly good supply of oxygen is still obtainable by causing the patient to lie on a bed or hammock out in the open air. When this is not practicable, we should have the windows of his bedroom kept widely open, resorting to extra bed-covering if required. In this way, a much larger amount of food can be taken with safety and advantage than when the patient is kept confined in an overheated room.

While insisting that the patient shall be kept out of doors as nearly constantly as possible, and, at all events, shall always, night and day, have an abundance of fresh air to breathe, whether within doors or without, it may be noticed that I have hitherto said little about the relative value of different airs or climates for cases of the disease under consideration. The reason is that I consider the importance of selecting a special climate for such cases greatly overestimated. Certain climates are doubtless somewhat more suitable than others for diseases of the lungs, but the difference is much less than is commonly supposed. The germ-laden air of crowded cities is naturally less curative than that of the country, seashore, or mountain. The purer the air the better, and contrary to a prevalent notion, the colder the air the better, provided only the patient can and will educate himself to be out in it and breathe it freely. It is said that the only climate in the world in which pulmonary tuberculosis does not exist is that of Iceland.

It is true that changes of climate exert a powerful stimulant action upon nutrition for a few months especially. Hence persons afflicted with pulmonary disease who have means to travel can often benefit greatly by changing from the seashore to the mountains or *vice versa*, after they have ceased to improve as at first. But to send tuberculous patients with

slender purses to distant resorts in the hope of finding some peculiar or magic virtues in the air of the place different from those in their own is usually as disappointing as it is cruel. Such patients as can ill afford the luxury of travel, if still in an early and curable stage, should be urged to lead an outdoor life in any locality (preferably away from large cities) where they can do so most conveniently and economically, and where the climate is not so rigorous as to prevent such a mode of life. If they are in a far advanced and hopeless stage they should be made as comfortable as possible in their own homes.

About twelve years ago a clergyman resident in Delaware came to Atlantic City with a diagnosis of pulmonary tuberculosis, made by a prominent specialist in Philadelphia, and sought my advice. It was a plain case, a large part of one lung being consolidated; but softening had not begun. At that time I had given little thought to the subject of diet in such affections, but poor parsons are not likely to be overfed. I told him to give up his pulpit for a year and go into the country, spending his time on horseback or in any way most agreeable to him, so long as he remained in the open air. He was also to keep up counter-irritation over the affected lung. He took the advice, and got well, and was able to resume his work by the end of the year. I have never seen him since, but he often sends me a box of the best Delaware peaches, accompanied by a letter full of gratitude to me for having shown him the way that led him back to health.

AN EXPLANATION OF THE GREAT FREQUENCY OF RICKETS AMONG NEAPOLITAN CHILDREN IN AMERICAN CITIES.[1]

By IRVING M. SNOW, M.D.,
of Buffalo, N. Y.

All American physicians who are active in hospital or dispensary life have noticed the great frequency of rickets among Italian patients. A very large proportion of the children of this nationality present well-marked symptoms of rachitis. Indeed, the most severe cases of rachitic deformity seen in orthopedic practice are from Southern Italy. This peculiarity of Italian children is all the more interesting because the disease was, until recently, only occasionally seen in this country, and is still rare among Anglo-Americans. In the monotony of digestive and respiratory disorders of a children's clinic it is safe to predict that in nearly three-fourths of the Italian children the disorder for which they are brought will be associated with rickets, and that this is the only pathologic difference between them and the rest of the community.

The study of the process of acclimatization of the various nations of northern and southern Europe that enter into the composition of our cosmopolitan population is as yet incomplete. Nevertheless, it is certain that any race not inured to our bleak northern climate must not only change its dress and regimen of life, but undergo a kind of cellular transformation in order to be in harmony with its environments and to preserve a vigorous physique in the second and third generations. Adults may endure extreme heat or cold, and be transplanted either to the tropics or the Polar Seas without harm, but this is not true of the children of the first generation, who endure very badly any marked change in the air to which their ancestors have for centuries been accustomed. History records many instances of the physical decadence of northern people who have migrated to semi-tropical regions.

Rachitis must be regarded as a serious condition in a child, as a constitutional deterioration, localized in the skeleton, muscles, nervous and digestive systems. A rachitic child has a lessened resistance to all of the acute infections diseases, especially those involving the respiratory tract. If rickets be increasingly prevalent among our city poor, and if it shows itself in its most serious phases in any one particular class or nationality, the fact is worthy of earnest scrutiny and investigation.

In the study of rachitis among Italian children in American cities, it is, of course, necessary to determine (1) the proportion of rachitic children among Italians; and (2) the proportion of rachitic children among other nationalities. Lastly, if rachitis be most frequent among Italians, the various supposed causes of the disease should be analyzed, to discover what especial factor, as diet, climate or habit of life, is chiefly in operation to produce this constitutional dyscrasia.

The object of this article, after indicating the degree of the prevalence of rickets among the various races of our population, is to show that the true reason for the very frequent development of the disease in Italians is found in the fact that it is the effect of our cold, damp, northern climate upon the offspring of a race that has lived for many hundred years in the warm, dry, sunny air of Naples and of Sicily. It is the physical deterioration of a southern race in a northern climate. I hope to be able to prove that the usual causes of rickets—city life, improper feeding, acute or chronic digestive disorders, bad air, crowding in dwellings, uncleanliness, infectious disease—which produce rachitis in a moderate percentage of the children of the northern races, act with far greater frequency and virulence

[1] Read before the meeting of the American Pediatric Society, held at Washington, D. C., May, 1894. Printed by courtesy of the Archives of Pediatrics.

upon the first generation of Neapolitans born in America.

To ascertain the exact ratio of rachitic children among Italians and other nationalities, I shall present the statistics of my dispensary service for a year.

Total number of children under three years, 200: Italians, 108; other nationalities, 92. Of the Italians, 76, or 70 per cent., were rachitic. Of mixed nationalities 11, or 12 per cent., were rachitic.

The parentage of the latter class was Scotch 1, American 1, Jewish 1, German 2, Irish 2, Polish, 3, not noted 1. Nearly all of the children were born in this country, but were chiefly of foreign extraction. My diagnosis of rickets was made after a careful examination of each child, and was based on well-marked beading of the costo-chondral articulations, craniotabes, etc. Characteristic transverse constrictions of the thorax were invariably more pronounced among the Italians—all of the cases of craniotabes and genu valgum or varum were among them. Whole families of children, as seen in successive years, were affected, so that rachitis was not only more frequent, but also more severe among Italians.

Of the seventy-six rachitic Italian children all had the classic rosary, and most of them were fat; many of them showed extreme muscular weakness, and were late in holding themselves erect and in walking; eighteen had transverse constriction of the thorax, with extreme narrowing and deformity of the chest; four had craniotabes, one with hydrocephalus; six had genu valgum; eight extreme muscular weakness; three enlarged spleen; two enlarged liver.

I was unable to discover that rickets in the Italians had any effect in delaying dentition. Most of the Neapolitan babies developed their teeth early, and without disturbance.

Eleven children, not Italian, all had the rachitic rosary; two had transverse constriction of the thorax. There was no craniotabes or pronounced limb-deformity among them.

The proportion of rickets among children of other races, 12 per cent., is small, and is probably insignificant as compared with that found in the densely populated cities of the Atlantic coast. In Buffalo the tenement-house class is relatively small; the houses are nearly all detached; and very little real destitution exists, even among recent emigrants.

Parry, in 1878, found 28 per cent. of all children brought to the Philadelphia Hospital to be rachitic; 20 per cent. of the children coming to autopsy in the New York Foundling Asylum showed rachitic changes in the bones.

Having demonstrated something of the prevalence of rickets in Buffalo, 70 per cent. of Italian and 12 per cent. of the children of other nationalities, we may next inquire more precisely into the antecedents, environments and mode of life of the Italians in their original home. Nearly all of the Italians in Buffalo emigrated from the country districts about Naples, the modern Italian province of Campania; a very few came from Sicily. None, to my knowledge, came from the cities of Naples or Palermo, and none from Central or Northern Italy. It is, therefore, understood that the Italians alluded to in the paper are Neapolitans. Further, the Neapolitans differ as widely from the Tuscans or Piedmontese in temperament, mode of life, and in climatic surroundings as do the citizens of Boston, Mass., from those of Charleston, S. C. The climate of Turin, in Piedmont, is sub-Alpine, and in the winter months is colder than that of Copenhagen.

We may now raise the question as to whether the frequency of rickets in Neapolitans is not merely a racial peculiarity, a phase of the southern Italian constitution in infancy. Upon this point I shall quote from Hirsch's *Historical Geographical Pathology*. In this work it is declared "that rickets exists everywhere, although most common in Europe and North America, in the temperate zone; that a cold, damp climate, subject to frequent changes, is favorable for its development, as is shown by its existence in endemic form in England, Holland, France, Germany, Austria, and Northern Italy."

Rickets is extremely rare, except in a few great cities, in Southern Italy, Spain, Greece, Egypt, Syria, and among the half-starved vegetarian people of Hindostan, China, and Japan. Rachitis is rare at high altitudes and in the extreme north, and is found in endemic form in large cities. Its absence in tropical and semi-tropical regions is contrasted with the great infant-mortality from all kinds of diarrheal diseases in these climates. Hence, as rickets is rare in the districts of Southern Italy, whence my patients are drawn, and is present in 70 per cent. of the first generation of Neapolitans born in this country, being nearly six times as frequent among them as among Anglo-American, Irish, Germans, Poles, and Canadians, some especial cause must exist to produce this grave deterioration in physique and to intensify the so-called blood-irritant or other cause of the disease. I shall enumerate the various factors that may play a rôle in the etiology of rachitis, to discover if the endemic character of the disease among Neapolitans in North American cities be the result of any one cause.

According to Cheadle, any injurious influence operating in not too sudden a manner on an infant may produce rachitis. The Italian colony in Buffalo (including between 4000 and 5000 persons) lives near the harbor, on damp ground, in old two-storied and three-storied tenement-houses and frame

cottages abandoned by the Irish. Nevertheless, the population in this neighborhood does not exceed 100 to the acre, as in the vicinity there are large open spaces, wide streets, and railroad-yards. The parents are strong, healthy, young people. The women are well-shaped and have easy labors. I can find no ground for believing that there is any hereditary weakness of constitution or tendency to rachitis. All of the adults appear well nourished. The fare includes soups, meat, bread, cheese, and vegetables, and is as plentiful, if not as expensive, as the food of the average American laborer.

Crowding in dwellings is more common among the Italians than among the rest of the community. A family of five or six usually occupies two rooms, the cooking and eating being done in one room and the other being used for sleeping. It goes without saying that from our standard of living their dwellings are dirty, overcrowded, and poorly ventilated.

The babies of the family are housed for a large part of the year in cold or rainy weather, and must continually breathe a polluted atmosphere, a circumstance that undoubtedly would depress an infant's health. This point will be discussed later in connection with climate. If overcrowding in sleeping-rooms and lack of fresh air were the sole cause of rachitis, it would be nearly universal among all recent emigrants from Ireland, Poland, and among the lower class of Hebrews, as well as among Neapolitans.

Most of the Italians say that they are better fed and clothed in America and that their sleeping-rooms are not as crowded as the small, smoke-filled hovels inhabited by the laboring-class in Naples, and are better ventilated.

Concerning the hygiene of the skin, the Italian babies were never as clean or as well cared for as the average American, Irish, or German. However, to say that they were, as a class, filthy would be untrue. They were warmly clad in winter, being usually swathed in a long, thick roll of woollen cloth.

Artificial diet, the feeding of infants with cows' milk, condensed milk, starchy or dextrin food, with an excess of carbo-hydrates and a deficiency in fats, has been rightly held to be a frequent cause of rickets; yet most of the Italian children received the ideal infant-food, breast-milk.

Analysis of food of Italian children under one year. Total number, 59.

Rachitic, 36: suckled, 21; suckled and fed, 8; artificially fed, 7. Not rachitic, 23: suckled, 17; artificially fed, 6.

Prolonged nursing cannot properly be held to be a cause of rickets, as in Japan, where children are suckled for two or three years, rickets is scarcely ever seen. A small proportion of the Italian women nursed their children for from fifteen to eighteen months. It was common to see rickets in children whose digestion was apparently good and who received no other food than breast-milk. Nearly all of the artificially-fed babies received some breast-milk up to the age of twelve months, the milk being supplemented by soups, condensed or cow's milk or gruel. The quality of the breast-milk of the Italian women may be questioned, as it was not analyzed; yet the evidences of poor milk, deficiency in fats, and excess of albuminoids, were not shown by any usual symptom, stationary or diminishing weight, or habitual vomiting. On the whole, the rules of a proper infant-dietary were no more frequently violated among the Italians than among other races; indeed, the Italian babies were more frequently breast-fed than the remainder of the dispensary patients.

Influence of intercurrent diseases. As a child is seldom brought to a medical clinic for rickets itself, I will state the various conditions for which the Italian children were treated. Total, 76.

1 pneumonia; 21 diarrhea; 5 dyspepsia; 3 meningitis; 9 bronchitis; 12 whooping-cough; 1 congenital heart-disease; 3 tonsillitis; 1 typhoid fever; 1 hydrocephalus; 1 Pott's disease; 2 syphilis; 6 extreme muscular weakness; 2 otorrhea, 1 eye-trouble; 1 injured spine; 4 not recorded; 1 cerebral monoplegia; 1 limb-deformity.

Pulmonary diseases, bronchitis and bronchopneumonia, complicating measles and whooping-cough, as seen in the dwellings of the Italians, were frequent and fatal among them; yet the large mortality from respiratory diseases among these children might properly be regarded as due to the weak respiratory muscles and the soft ribs of rachitis.

Digestive disorders, chronic vomiting, and acute or chronic diarrhea were no more severe or more frequent among Italians than among other patients. It is nevertheless true that any digestive trouble is more prolonged in a rachitic baby and yields less readily to treatment than in a previously healthy child. I was unable to observe that the digestive disorders of these rachitic babies were other than intercurrent affections. The rachitic children were usually brought for some acute malady of a few days' or weeks' duration, and it was evident that the constitutional disease had developed slowly and without marked symptoms.

When all these causes of rachitis are reviewed it is certain that enough are in operation to produce the disease in a moderate proportion of Italian children as well as in those of other nationalities. The conditions are insufficient to account for the fact that rachitis is nearly six times as prevalent in Italians as in other classes of the community, and is present in 70 per cent. of a race with whom the disease is rare in the mother country.

I have not yet discussed the influence of climate in the etiology of rachitis, and this Theobald Palm regards as the chief cause. Virtually all of my patients were born and lived in the same climate. The disease is rarest among Anglo-Americans who have lived in the country for generations. It prevails to a moderate extent among the children of English, Irish, Germans, and Poles. These races are inured to the cold, changeable atmosphere of Northern Europe. It is far different, however, with the Southern Italian, who has lived for many centuries under the clear skies and in the warm sunshine of Naples and Sicily. In these fortunate regions men, women, children, and babies are out of doors most of the year.

Besides the differences in climate between Buffalo and Naples, which are very great, the Italian babies in our American cities are housed for a large portion of the year on account of inclement weather, and breathe damp, foul air, which is always too cold or too hot. If there be any law of heredity, a race whose vitality and nutrition are accustomed to a semi-tropical climate and pure warm air cannot thrive amid such surroundings. The change is too sudden and acute, both in temperature and in atmosphere.

What are the differences in climate between Naples and Buffalo? I have constructed a chart indicating, in rather a schematic way, the temperatures and rainfall of the two cities, whose climate is a fair index for the surrounding districts.

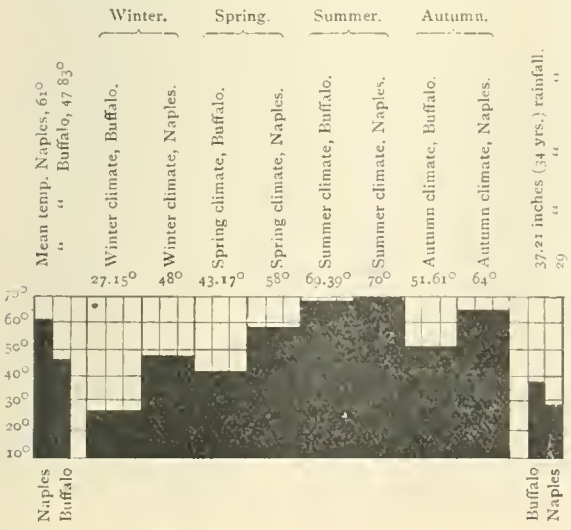
CLIMATOLOGY OF NAPLES AND BUFFALO CONTRASTED.

Naples: Dry and warm in winter; mild, with occasional rainy days in November and latter part of January and in February. Summer atmosphere tempered by sea-breezes.

Buffalo: Climate tonic and bracing; changeable and uncertain at all times.

	Rainy.	Cloudy.	Fine.
Naples	100	120	145 days.
Buffalo	289		76 "

Temperature—(of Buffalo, average 18 years; of Naples, 20 years):



The situation of Buffalo, in 42° 53′ northern latitude, on Lake Erie, exposes it to bleak winds in the autumn, winter, and spring; the annual rainfall is 37.21 inches, 8.21 inches greater than that of Naples, which is situated in 40° 52′ northern latitude. In Buffalo variations in temperature are very great and very sudden. The mean temperature for a year in Naples is 61°, in Buffalo 47.83°—that is, 13.17° lower than in the Italian city. The winter temperature of Naples is 48°, that of Buffalo 27.15°; the American city is thus 21.85° colder. The mean temperature in spring in Naples is 58°, in Buffalo 43.17°; Buffalo has the colder temperature by 14.83°. In summer, curiously enough, the mean temperature of both cities is nearly the same, about 70°. The autumnal difference is 12.39°, Naples having a mean temperature of 64°, Buffalo 51.61°. Between the winter and summer climate of Naples the variation of temperature is 22°, of Buffalo 42.24°. Again, Buffalo has only 76 clear days in a year compared with Naples, which has 145.

The intrusion of a southern race into a northern climate is an occurrence that has few parallels in history. It is reasonable to suppose that serious changes in physique seen in the first generation would follow a change of residence from an out-of-door life in a semi-tropical country to the gloomy skies and long winters of the North Atlantic and lake cities. In proof, I may point to the rapid deterioration of negroes in cold climates, or to the physical decay of the Anglo-Saxon race in India or in the hot climate of North and South America.

Whatever may be the disadvantages of life in warm climates, whether of crowding in dwellings, bad drainage, water, and food, it is certain that rickets is seldom developed among the natives of Southern Italy, Egypt, and India. The probability is that the misery, ignorance, and neglect of hygiene amid which the children are reared are in some degree offset by the bright, warm sunshine. To secure a perfect development for the young of the human species a large portion of the day should be spent out of doors, and, if possible, in the sun. This cannot be accomplished with the children of the city poor, and it is to this lack of pure air and sunlight that we may attribute the spread of rickets in densely populated urban communities. With the first generation of Neapolitans born in American cities, all of the causes of rickets—improper food, bad air, depression caused by infantile maladies—are intensified and accentuated, and the presence of rachitis in seven-tenths of the Neapolitan babies in Buffalo indicates a constitutional deterioration from a great and sudden change in environment.

In plants and animals, adaptation to a different climate is never effected suddenly—a number of healthy adult individuals are first transplanted to

some intermediate station, where they may grow for several years. Some of the stock may develop vigorously, some deteriorate. As soon as the stock has been exposed to all the vicissitudes of climate the healthiest individuals may again be moved farther north, the necessary nursing and protection being of course given. Man has certainly greater powers of adaptation to climatic changes than animals or plants; still the history of the early years of a migration to a different climate, conducted even under the hygienic laws of a high civilization, is usually one of suffering and great infant-mortality.

The Teutonic races have always fared best when they have found a climate like that of their original home. Man is best able to maintain his health and multiply when he travels in isothermic lines. Migration either to a warmer or to a colder climate should be conducted slowly, step by step, allowing one or two generations to intervene before the extreme is reached.

In conclusion, I shall quote from Theobald Palm's excellent article in the *Practitioner* on the "Etiology of Rickets." He says: "The effect of light upon the human organism is obviously more complex than its direct chemical action upon the tissue immediately exposed to it. The exhilaration which we experience in bright weather, and the depression caused by dull, gray skies, must have a corresponding physical change in the nutrition or molecular condition of our nervous centers, and these react upon the general nutrition. The continuous withdrawal of a due measure of this normal stimulus to healthy functional activity must produce upon a young, actively-growing organism serious and far-reaching results." He also states that as light is essential to the well-being of the growing organism, the exclusion of light is a condition of development of the same organism in the embryonic stage. He suggests that the deficiency of light and sun after the embryonic stage is past, when nutrition is dependent on chemic changes of light and air, lead in plant and animal to partial continuance of the embryonic state, as seen in man and higher animals in rickets in the continued growth of embryonic cartilage instead of its conversion into bone.

VITAL STATISTICS OF THE NEGRO.

BY FREDERICK L. HOFFMAN,
OF HAMPTON, VA.

IN THE MEDICAL NEWS for April 7, 1894, p. 389, Dr. M. V. Ball discusses at some length the differences in the mortality of the white and negro races, and maintains that these differences are due more to social causes and environment than to permanent race-characteristics. He advances the theory that if the negro were placed, from childhood up, under the same social influences as the white man the present differences in the mortality would probably disappear. Do these conclusions bear examination in the light of well-known facts on the subject? Or is it possible to bring forward proofs to the contrary and to establish the position held by a large number of writers on the subject, that there is among the negroes a well-recognized race-proclivity to disease and death which manifests itself even when the negro is placed under exactly the same conditions, social and economic, as the white race. To do this will be my aim in this paper.

In the first place it will be necessary to bring forward some figures as to the relative mortality of the two races. From a recent report of Dr. J. S. Billings I have compiled the following table, showing the respective death-rate (stillbirths included) for a number of Southern cities:

	Rate per 1000.	
	White.	Colored.
Washington, D. C., 1890 . .	19.79	38.22
Charleston, S. C. " . .	24.75	53.94
New Orleans, La. " . .	25.41	36.61
Richmond, Va. " . .	22.25	40.80
Memphis, Tenn. " . .	23.37	29.97

According to this table the difference in the mortality of the two races is anywhere from 25 to more than 100 per cent.—a difference large enough to warrant serious consideration. Are these differences accidental or permanent? An investigation of the vital statistics of any city in the South will show that year after year, for the past twenty years, this difference has been about the same.

In the following table I have brought together the death-rates, according to race, for the two cities, Washington, D. C., and Richmond, Va., for the period from 1876 to 1892.

	Washington, D. C.[1]		Richmond, Va.[2]	
	White.	Colored.	White.	Colored.
1876 . .	19.54	40.78	22.60	31.10
1877 . .	19.97	38.22	20.70	32.50
1878 . .	19.28	37.37	19.20	29.90
1879 . .	19.05	36.90	20.90	31.90
1880 . .	17.63	35.71	20.70	36.30
1881 . .	18.18	31.27	20.70	41.80
1882 . .	18.91	34.54	20.70	36.70
1883 . .	17.97	30.69	19.70	36.50
1884 . .	19.71	32.29	20.30	37.10
1885 . .	19.97	34.45	20.70	32.40
1886 . .	17.96	32.35	19.10	31.40
1887 . .	17.74	31.15	19.90	36.40
1888 . .	18.52	30.16	19.90	33.60
1889 . .	15.96	30.49	18.30	33.60
1890 . .	17.25	32.87	22.30	37.80
1891 . .	18.27	32.68	20.70	34.10
1892 . .	19.67	31.19	19.20	33.10

In no instance does the colored rate approximate the white rate. Without exception the colored rate exceeds the white rate by a ratio of from 50 to 100

[1] Annual Report of the Health-office for 1892.
[2] My own calculation for inter-censal years.

per cent. On the basis of the statistical law of large numbers the assertion may be made that the cause of such a difference must be fundamental and permanent rather than social and transient.

But Dr. Ball maintains that if the social conditions were the same this difference would disappear. We, however, possess in the records of the United States Army proof to the contrary—proof so convincing that it will be hardly necessary to add anything further in support of the theory of distinct race characteristics. The following little table shows for three census years the mortality in the United States Army according to color. The ratios are based on 1000 of mean strength for each race:

	White.	Colored.
1870	13 5	20.6
1880	9.9	19.5
1890	8.4	11.5

I cannot do better than to quote at some length the language of the Surgeon-General in regard to the characteristics of the negro race. He expresses himself as follows in his report for 1889 (p. 18):

"The death-rate of people of African descent is always higher than that of the whites living in the same settlement. This is ascribed, for the most part, to the comparative poverty of the colored people, which crowds them into their dwellings in the less desirable part of the locality. *It would seem, however, from the medical report of the army, that there is a race-proclivity to disease and death;* for, although the colored troops are in all respects subject to the same influences as the white troops at the same station, the cases of sickness and mortality are greater among them than among the white troops. Both sets of men are selected by the same recruiting officers, sent to the same depot, transferred for service to the same posts, lodged in similar quarters, furnished with the same allowance of clothing, use the same water and the same food-supplies, perform the same duties, and are subject to the same exposure, yet the admissions to sick-report were 1.464 per 1000 for the colored, and 1.249 per 1000 for the white troops. The non-effective were 44.56 per 1000 as compared with 27.67 for the white troops, and the death-rate 13.66 per 1000 for the negroes, as compared with 7.55 for the white troops."

Coming from such a recognized authority and in such an emphatic manner, the remarks just quoted deserve the most careful consideration of the student of the subject. But the same report contains another proof of this race-proclivity to disease and death. As will be noted in the next table, for the British troops in the West Indies, the mortality and morbidity of the negro under conditions exceptionally favorable to him are still largely in excess of those of the white race.

MORTALITY AND MORBIDITY IN THE BRITISH ARMY IN THE WEST INDIES (ratio per 1000).

		Admission to sick-report.	Deaths.	Discharges.	Non-effective.
1886	White,	1.168	14.70	11.76	55.09
	Colored,	1.292	19.64	16.07	57.25
1876–85	White,	0.893	15 42	13.95	44.68
	Colored,	1.074	15.38	26.79	58.38

These figures are supported by the mortality-reports of the islands in the West Indies. From the blue-books, registration-reports, and annual reports, I have compiled the following table, which I believe is the first attempt to present in tabular form the mortality for a number of West Indian colonies. It has been impossible in the table to separate the races, but the white population forms such a small percentage that the result is but slightly affected. The rates are per 1000 of the living population:

Antigua,	35.5	Virgin Island,	19
Barbuda,	30	Martinique,	35
St. Kitts,	42	Guadeloupe,	22.5
Nevis,	35	Trinidad (1893)	27.6
Dominica,	18	Jamaica (1893)	20.9
Monserat,	20	Barbadoes(1891)	37.26
Bahama Islands	27.3		

We have here the returns from a large number of islands, which almost without exception show a rate above 20 per 1000. If we take into consideration possible omissions in the registrations, the figures presented will fall below rather than above the actual condition. As life in the West Indian Islands is to the negro a paradise on earth, being an out-door rural life, with little manual labor attached, we may well ask the question what his death-rate would be if he were placed in densely populated cities. It is difficult to ascertain the actual natural increase in the population, due to the constant inter-migration between the islands and the influx of coolie population. If predominance of females, however, be considered a factor as showing a population making but a small natural increase, the fact that most of the islands have an excess of females might be cited in support of such a theory.

But, to come back home again, let us consider the effect of similar social surroundings in the two races. For Richmond, Virginia, I have recently compiled the data for the different wards, and find that those wards that contain the largest colored element also show the largest death-rate, while the "white wards" of the city show much more favorable rates for the colored population. But the fact is that there still remain the same differences between the two races; that is to say, if the white rate goes down so does the colored rate, but the relative position of each remains unchanged. This will appear clearly from a study of the next table.

Of course it is not possible to trace the population distinctly, but it may be accepted in a general way that the first three wards represent the so-called "better part" of the city, while Jackson ward in particular is the so-called "Africa" of Richmond. Thus, placed under better social and sanitary conditions, the death-rate will diminish, but will still be from 50 to 100 per cent. in excess of the white rate. Two recent reports of the Census Office on the

vital statistics of Baltimore and Washington, New York and Brooklyn show similar results.

Mortality of Richmond, Va., by Wards and Color.

(Rate per 1000 of population, 1890).

Wards with large white population:				
Madison,	white rate,	18.3	Colored rate,	30.0
Monroe,	" "	14.8	" "	21.7
Clay,	" "	18.0	" "	29.0
Wards with large colored population:				
Jefferson,	white rate,	25.5	Colored rate,	37.0
Marshall,	" "	24.0	" "	39.0
Jackson,[1]	" "	38.9	" "	40.0

If we now proceed to consider the influence of a high death-rate on the average duration of life, it will be seen by the table that follows, for the city of Washington, D. C., that there is an enormous difference between the length of life of the two races. I give the data for four different years, covering a period of thirteen years:

Average Age of White and Colored Decedents in Washington, D. C., 1881–92.

	White.	Colored.
1881	32 years.	20 years 11 mos.
1885	32 years 3 mos.	22 " 7 "
1890	33 " 8 "	22 " 10 "
1892	34 " 6 "	23 " 4 "

On the basis of these figures a white man, on an average, has a longer duration of life by some ten or twelve years than the colored man—a difference that has been recognized, and has been verified by subsequent experience, by all the life-insurance companies engaged in business on the so-called industrial plan. The following are the figures of the Prudential Insurance Co., of Newark, N. J., as quoted in the *Journal of the American Statistical Association*, vol. iii, p. 351:

Loss in Claims per $1000 Insured, 1883–93.

	White.	Colored.		White.	Colored.
1883,	15.30	23.41	1889,	15.45	21.43
1884,	15.27	18.75	1890,	17.11	21.49
1885,	16.04	22.47	1891,	16.71	21.44
1886,	17.90	24.44	1892,	17.91	21.32
1887,	16 59	21.49	1893,	17.34	17.89
1888,	16.60	21.68			

We have here another proof of the permanency of the difference in the mortality of the two races. Without exception the colored rate is in excess of the white rate, and that, too, in view of the fact that a medical examination was made in most cases, and that, therefore, the persons insured were much more nearly similar than the population in general.

If we now consider the mortality by groups of ages we meet with another instance of racial characteristics. On the supposition, generally accepted by economists, that the period of life below twenty is of little economic value, it will be important to a population to maintain as large a number of individuals as possible beyond the twentieth year. From the report of the Health-office of the District of Columbia for 1892, it appears that 59.90 per cent. of white males and 57.88 per cent. of white females survive the twentieth year against 38.51 per cent. of colored males and 42.24 per cent. of colored females. The economic loss that must result from such excessive mortality below the age of twenty it is difficult to estimate. If, further, we consider the age of forty as the end of the productive period, and as that portion of life's span in which we should enjoy the result of life's labor, we find, on examination of the same report, that 43.36 per cent. of white males and 38.94 per cent. of white females survive the fortieth year, against a percentage of 24.25 colored males and 24.27 colored females.

Both of the instances cited will confirm the assertion made in the beginning, that the characteristics of each race are fundamental, and not merely due to environment or lowly social condition. This point is brought out more clearly if we bring into juxtaposition the average duration of life of native and foreign and white and colored, which I have done in the next table for three American cities:

Average Duration of Life by Nativity and Color for Three American Cities.

	Boston, Mass.		Providence, R. I.		Washington, D.C.	
	Native.	Foreign.	Native.	Foreign.	White.	Colored.
1888,	32.66	31.01	35.66	30.29	33.16	22.90
1889,	31.56	31.01	36 18	31.19	32.66	21.90
1890,	33.75	32.32	35.14	30.03	32.66	22.83
1891,	34.47	32.51	36.88	31.01	34.58	22.75
1892,	32.86	31.45	36.39	32.70	34.50	23.25

Without exception, the native and foreign rates differ but slightly, while not in a single instance does the native or foreign rate approach the high rate of the colored population. The fact is well known that the foreign element of our large cities forms the principal population of the slums; yet the general death-rate does not seem to be affected by the mode of living. If the high rate of mortality among the colored population be due in the main to unfortunate social and economic conditions, why should not also the foreign element be affected in a similar manner? It is true that the Irish population shows some similarity in its mortality to the negro population, but until the collected data on the subject have been published a consideration of this point would be inadvisable.

Coming down to specific causes of death, the special liability of the negro to tuberculous disease is so well known as to need but passing mention here. From an article of mine on the "Vital Statistics of the Negro" (*Arena*, April, 1892) I quote the following table, showing the percentages due to this cause for six leading Southern cities. The figures repre-

[1] The high white rate for Jackson ward for 1890 was abnormal. The normal rate is from 22 to 26 per 1000. See Richmond Dispatch, July 17, 1894.

sent the percentage of deaths due to pulmonary tuberculosis to the total mortality:

MORTALITY FROM PULMONARY TUBERCULOSIS, BY RACE.

	White.	Colored.
Washington, D.C.	0.11	0.16
Atlanta, Ga.	0.11	0.15
New Orleans, La.	0.12	0.17
Charleston, S. C.	0.08	0.15
Memphis, Tenn.	0.12	0.18
Richmond, Va.	0.10	0.11
Average	0.10	0.15

We have here another striking proof of the constitutional difference between the two races, but the following table, compiled from the *Surgical and Medical History of the War*, will illustrate the point more forcibly:

DISEASE AND MORTALITY OF THE U. S. ARMY, 1861–65.

(Per cent. of total cases treated.)

	White.	Colored.
Pulmonary tuberculosis	0.39	0.91
Typhoid fever	0.36	0.56
Chronic diarrhea	0.16	0.27
Inflammation of the lungs	0.24	0 32
Average	0.29	0.51

Here again we meet with a proclivity to disease and death considerably in excess, *in every instance*, of the white rate. Need more proof be brought forward to maintain the assertion that the negro and the white man differ fundamentally in their physical organization and power of vital resistance? I could quote authority after authority to prove that such is really a fact. It was stated, as far back as 1845, of the freed negro in the Eastern Pentitentiary of Pennsylvania, by President Matthew L. Bevan, that the increase in deaths comes from the blacks. The increase in the mortality is found in the fact that the colored inmates from the County of Philadelphia are *so constitutionally diseased* as under any and all circumstances to be short-lived from their character and habit.—De Bow's *South and West*, vol. ii.

The condition of 1845 is the same to-day, and the city negro brought into direct competition with the white race has usually but one avenue out of his dilemma—the road to prison or to an early grave. Crime among the colored population of our large cities has been considerably on the increase; and, like his mortality, his morality differs fundamentally from the morality of the white race. Dr. A. Corre has made a study of the negro in the French West Indies, and comes to the conclusion that "the negro and the white man have *distinct physical organizations*. and, as a result, *distinct social aptitudes* (*Le Crime en Pays Créoles*, Paris, 1889). A similar study of the negro criminal in this country would lead to similar conclusions. The Northern cities contain the bulk of the negro population in the Northern States. In the large cities he crowds into a few wards, and forms his little Africa, no matter where he may be. If we select the four States of Massachusetts, Rhode Island, New York, and Pennsylvania, we find on examination that of the total colored population of these four States 33 per cent. live in thirty-nine wards of six leading cities. These same thirty-nine wards contain 25 per cent. of the total colored population of the nine North Atlantic States. If we take up the statistics of the State of Ohio we find that twenty wards of six principal cities contain 27.4 per cent. of the total colored population, while the same twenty wards contain white population. If we consider the population only 8 per cent. of the total of the six cities we find that the same twenty wards contain 51.6 per cent. of the total colored and only 14.3 per cent. of the total white population.

But Chicago furnishes the most surprising condition. Here we find 64 per cent. of the total colored population of the city massed together into the First, Second, and Third Wards, which are the very slums of the city. The same three wards contain only 6.3 per cent. of the total white population. What else but a high rate of mortality and low degrees of morality could be the result of such tendencies of a race wholly unprepared for the intensity of the struggle for life in our large cities. If we take, for example, the proportion of criminals to the total population we shall find on examination of the report of the Chicago Police Department that the proportion of arrests of persons of color is 1 to every 2.7 of the colored population, as contrasted with a ratio of 1 arrest to every 19.1 of the white population. The negro population of the city increased 128 per cent. during the decade 1880–90, while the number of arrests increased 305 per cent. The white population increased 139 per cent. during the same period, but the number of arrests increased only 154 per cent.

For other cities the condition is very much the same. For the State of Pennsylvania the ratio of white convicts to the white population for 1890 was 1 to every 3504, in contrast with a ratio of 1 colored inmate of a penitentiary to every 370 of the colored population. In the city of Washington the percentage of illegitimate to total births is 26.40 per cent. for the negro and 2.5 per cent. for the white race. Yet the negro has been under religious influence for two hundred years, and in the capital he has had all the exceptional opportunities for mental and moral advancement. Does it seem reasonable to suppose that his present high rate of mortality and low standard of morality are due solely to environment?

On the strength of all the facts that are here brought together I cannot but repeat that the

differences are physical and permanent, and if a modification or change of his present-day tendencies is possible, the negro will first have to learn obedience to the laws of morality and hygiene, and adherence to the principle of duty rather than to the gospel of the rights of man. What to the white race is liberty is to the negro nothing but license, and if he has abused the freedom that was given him, it is not he who is to blame so much as those who had his education in their hands. What the negro needs is education—*genuine, not spurious*—and a sounder teaching of the first principles of every-day morality. To effect a change in his present-day tendencies will take generations, but only on the principles that have preserved the Anglo-Saxon race from decay will he be able to raise himself to a higher level and preserve his race from ultimate extinction.

GASTROSTOMY BY A NEW METHOD.[1]

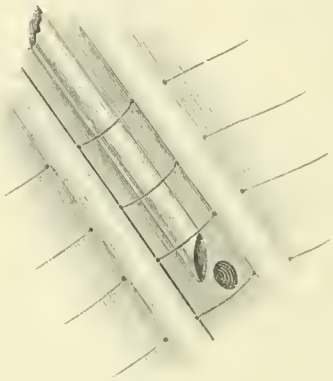
BY M. STAMM, M.D.,
OF FREMONT, OHIO;
PROFESSOR OF OPERATIVE AND CLINICAL SURGERY, UNIVERSITY OF WOOSTER, CLEVELAND, OHIO.

THE recent successful results of gastrostomy, thanks to improved methods, have made this a well-established operation in cases of carcinomatous or cicatricial stricture of the esophagus, and have prompted us to operate at an earlier time than in former years. Before the antiseptic period, among twenty-eight cases one alone recovered—or at least lived forty days after the operation. Since that time more fortunate results have been obtained, and it may now justly be maintained that a fatal issue is principally due to the fact that the operation has not been resorted to before the patient was too much reduced in strength.

Having eliminated the danger of sepsis, the next object is to overcome other sources of danger or annoyance. One important point in my mind would be to lessen the effects of shock in some cases in very feeble persons by feeding the patient as soon as possible after the operation through the fistula. The next and probably most important point would be to prevent the escape of food or gastric juice from the stomach, which would have a tendency to corrode and infect the wound. Quite a number of methods have of late been introduced with a view of obviating these sources of danger.

Hahn's method has for some time found favor with quite a number of surgeons. It consists in fixing the stomach to an opening made in the eighth intercostal space on the left side, so that the ribs perform the function of a valve. This was, no doubt, an improvement over the older methods, but, in some cases operated upon by Von Hacker, ulceration of the ninth costal cartilage resulted, and had these cases lived for a longer time serious mischief would very probably have ensued. Von Hacker, after this, tried to prevent leakage from the fistula by using the left rectus abdominis muscle for the formation of a sphincter, and was able to report twelve cases operated upon in this manner; the stomach, except in one case, not being opened until after an interval of forty-eight hours. In all of these cases recovery from the effects of the operation took place, but it was necessary to use an inflatable double rubber bulb to prevent leakage.

FIG. 1.



Method of Witzel.

Girard also makes a sphincter from the rectus muscle. Parallel to the operation-wound he dissects out strands of muscle-fiber about the thickness of a finger; these he crosses laterally, and draws the stomach through the sphincter-like opening. Ssabanejew makes an incision two or three inches in length along the left lower border of the ribs, beginning at the end of the ninth rib. He then pulls out the stomach by catching up a fold with a pair of intestinal clamps, and makes another incision near the sternal end of the sixth rib, from half an inch to an inch to the left of the mammillary line. With blunt instruments he separates the soft tissues between the first incision and the second, in this way forming a sort of tunnel. The parietal peritoneum is then stitched to the serous coat of the stomach at the base of the fold. The apex of the fold, after having been pulled through the tunnel, is stitched to the second incision. A small incision is afterward made into the stomach, and a drainage-tube is introduced.

The method of Kocher is somewhat similar to that just described. This surgeon makes a vertical incision, about four inches long, two inches above and to the left of the umbilicus; then he draws out a part of the stomach for about four inches. After closing the abdominal opening except for a distance

[1] Read before the Ohio State Medical Society at Zanesville, Ohio, May 17, 1894.

of about two inches, he stitches the stomach to the fascia and peritoneum with a continued suture, and then makes a channel in the manner adopted by Ssabanejew.

A procedure which has of late been highly extolled by some surgeons, and which so far has really given excellent results, is that devised by Witzel. Keen, of Philadelphia, in a recent article claims that this operation has reached such a stage of perfection that there can be very little room for improvement. From the description of his case, however, I see that he fed his patient for two days by rectal enemata—probably for fear that fluids might ooze out through the wound and produce infection. And yet I think that prompt feeding through the tube is a very important factor in some cases in feeble persons; at least, it impressed me so in a case in which I operated after Hahn's method a few years ago, in which the patient was *in extremis*. The case was one of cicatricial stricture caused by swallowing nitric acid, the patient dying from shock about twenty-four hours after the operation. I still feel that prompt feeding through the stomach might have averted the fatal result.

The operation of Witzel consists in establishing a canal between two folds of the gastric wall. A large surface of the stomach is drawn out through the abdominal wound, and a small incision is made into the viscus to admit a rubber tube of the thickness of a lead-pencil. This tube is stitched to the stomach with catgut, whilst the upper end projects from the external wound. Two parallel folds of the stomach are then taken up so as to envelop the

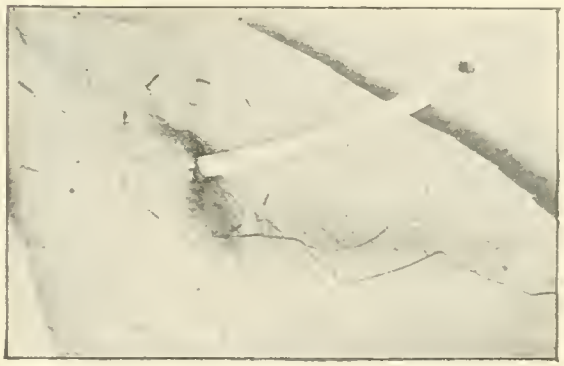
FIG 2.

Method of Witzel.

tube; their free margins are stitched together by three or four Lembert sutures and several ordinary sutures. The canal thus made is a little over an inch long, and is left exposed at the bottom of the wound. A number of sutures will then fix the stomach to the abdominal opening.

Some experiments upon dogs have suggested to me a plan of procedure based on sound anatomic principles, and which, if not better than Witzel's method, is at least equally as good. In the dog the result has met every point that it was *a priori* intended to accomplish. The first steps of the procedure are the same as in Witzel's, an incision about three inches long being made along the left border of the ribs. The point for the introduction of the rubber tube is marked with the knife by a slight incision simply through the serous coat of the stomach.

FIG. 3.



Around this point as a center, and at a radial distance of a little over one inch, a purse-string suture is introduced by means of a straight needle and strong silk, and including only the serous and muscular coats of the stomach. Next the opening in the stomach for the rubber tube, about the thickness of a No. 15 American scale catheter, is made, and the tube is fastened by a silk or catgut suture. The purse-string suture is now drawn together, and there results a double sphincter, which will guard against any leakage from the stomach. With about six interrupted sutures I stitch the stomach to the parietal peritoneum, and both ends of the purse-string suture, which so far served to hold and steady the stomach, are now armed with needles and passed through the entire thickness of the abdominal wall on both sides of the wound and then tied in a loop. This arrangement will anchor the stomach firmly in position, and the suture can be removed in eight or ten days.

The dog upon which the experiment was made was fed immediately after the operation. On about the fifth day the tube in some way escaped into the stomach, but from the day of the operation up to the end of two weeks, when the dog was killed, not one drop of fluid escaped through the fistula. The latter was found patent post-mortem. The whole stomach was removed and filled repeatedly with water, and, as I am able to demonstrate to-day, it stands the test very well, not one drop of fluid escaping. The fistula was slit open in the presence of some members of the Society, and showed the two sets of valves plainly.) In a case operated upon by Mikulicz

according to the method of Witzel, in which death took place six months afterward, the stomach, after removal from the abdominal cavity and being filled with water, did not stand the test so well, although fluid never escaped through the fistula during life.

A hint thrown out by Ewald might be well worth considering. In carcinomatous stricture of the esophagus he advises the making of a fistulous opening in the vicinity of the pylorus, so as to permit the introduction of food directly into the intestines by means of a rubber tube. His observations lead him to assume that in such cases the digestive power and the motility of the stomach are almost totally abolished, and that this viscus will only serve as an incubator for microbes, as microscopic examination of the contents of the stomach under such circumstances revealed the presence of pure cultures of putrefactive bacteria. He further advises the occasional washing out of the stomach through the fistula with a solution of boric acid, resorcin, salicylic acid, or similar agent, or the direct introduction of one of these through the mouth. Brandy swallowed in teaspoonful-doses may also act as a disinfectant.

CLINICAL MEMORANDA.

CELIOTOMY UNDER UNUSUAL CONDITIONS.

With a Report of Ten Cases.[1]

By GEORGE ERETY SHOEMAKER, M.D.,
SURGEON TO METHODIST HOSPITAL; GYNECOLOGIST TO ST. CLEMENT'S DISPENSARY AND TO THE HOSPITAL FOR EPILEPTICS.

I DESIRE to give some practical illustration of the problems that confront the abdominal surgeon and to present some cases of widely differing type, selected for purposes of illustration. All the cases reported recovered from operation. All are living except one, who lived a year and a half and died of facial erysipelas.

The first case represents some of the later developments of neglected pelvic inflammation and their final cure by operation.

CASE I. *Hydronephrosis from obliterated ureter; pyosalpinx and ovarian abscess surrounding the vermiform appendix; catheterization of ureter.*—E. L. P., aged thirty-five years, of good heredity, was married nine years, and had three children and one miscarriage. Her first labor, seven years ago, appears to have been followed by sepsis, since which she has had numerous attacks of pelvic inflammation, usually starting as severe pain in the right ovarian region, and centering around the umbilicus. These attacks have increased in severity and frequency during the past three years, resulting in practical invalidism. The last attack, having lasted about five weeks, brought her to the Methodist Hospital, where she presented a deplorable picture, emaciated, vomiting green, and at times bloody, bile-stained fluid; a large undermining bedsore over the sacrum; the tissues sloughing to the bone; irregular temperature to 101°; leaky skin and thready pulse. The abdomen was tympanitic and extremely tender, a semifluid mass filling the right half of the pelvis.

More than three weeks were consumed in the careful preparation for operation, by unloading the bowels, improving the stomach and securing a better appearance of the sloughing bedsore, which last was a representation of the general condition. Just here, I may say, that there is a golden time to operate, and careful observation alone will determine it in some of these desperate cases. It is not always as soon as the diagnosis is made.

I am convinced that it is wiser in acute peritonitis, when the case appears to have *already reached a standstill*, and when pus is not known to be present, to operate after the acute symptoms have subsided, if the condition of the patient warrants waiting. Also, in some profoundly septic conditions such as this, I am sure that I have saved life by waiting day by day, until by cleanliness and careful nursing a retentive stomach and a better tone have been obtained. In other words, it is safer to nurse an almost moribund patient a little if previous care has been wanting. This is not to be mistaken for an advocacy of delay after hemorrhage, or in progressive cases, such as acute suppurative appendicitis.

Operation, November 21, 1893. Everything in the pelvis was adherent by thoroughly organized adhesions to a mass which afterward proved to be the right tube and ovary riddled with abscesses and surrounded by hyperplastic tissue The cecum was with difficulty freed down to the vermiform appendix, which passed directly into the inflammatory mass and was surrounded by it. The appendix was ligated off at two points, and came away afterward with the mass. When afterward dissected out it appeared healthy. The exudate appeared to pass behind the peritoneum at the outer border of the iliac muscle, and a tough prolongation was here ligated off. Thick, green, highly offensive pus, several ounces in quantity, escaped from the largest ovarian sac deep in the pelvis; but as a continuous stream of hot water was led to this point by the irrigation-nozzle, and kept constantly flowing out of the wound during the remainder of the operation, no harm was done. Thick pus does not readily mix with water, and may be carried along bodily by a heavy stream. The left tube and ovary were allowed to remain, as they appeared to contain no pus. The right kidney-region contained a large thin-walled cystic tumor, with a rounded lower end, flattened in alongside the spine, apparently a hydronephrosis. There was not a sign of inflammation about the mass, and no adhesion existed over it. It was decided not to open it then through the loin, as from its contiguity the bedsore would surely infect the wound. The fluid was considered not to be pus, because no adhesions of surrounding viscera overlaid the sac.

The patient made an excellent recovery from the operation, and looked better from the first. The temperature touched 100° on the third day for the only time. A glass drainage-tube was employed.

The question as to the proper disposition of the hydronephrosis still remained after recovery from the celiotomy. One month later the woman was free from pain, was going about the ward, had gained greatly in flesh, and had a good appetite, but the kidney-swelling was unchanged. She was now etherized, put in the Trendelenburg position, to allow the distention of the bladder with

[1] Read before the Philadelphia County Medical Society, April 11, 1894.

air, after the method of Dr. H. A. Kelly, and the orifices of the ureters exposed after dilatation of the urethra.

I demonstrated to my own satisfaction that no urine was coming through the right ureter, which had apparently been occluded by the unusually dense inflammatory infiltration that had previously existed. It was determined not to incise the sac, for if the ureter were obliterated a permanent fistula in the loin would result, while there was every probability of atrophy of the kidney occurring if nothing were done. Five months have now elapsed, the sac in the loin is with difficulty recognized, and the patient suffers no pain. Urinary examination was negative, and the quantity of urine, diminished for a few weeks after the celiotomy, became normal and remained so.

A letter received from the patient to-day expresses her great satisfaction over her restored health. She feels better than for ten years, and has gained twelve pounds over the highest weight of seven years. She was not weighed when emaciated by sepsis.

The relatively small abscess in the abdomen, limited by adhesions, and which can be opened and drained with safety to the patient, is a condition common enough.

It is very rare, however, to see recovery follow when the pus has been diffused from diaphragm to pubis and across the full width of the abdomen, as in the following case of obscure but probably tuberculous origin. As recovery followed, a tuberculous cause is made probable, for septic cases of this extent *never get well.*

CASE II. *Recovery from diffuse purulent peritonitis, probably tuberculous.*—Miss A. S., aged twenty-two years, was previously healthy. She was tall, active, and well-formed, and weighed 160 pounds. Her mother died of pulmonary tuberculosis. While menstruating the patient had an attack of so-called *la grippe*, and five days later thoroughly chilled herself by a cold bath, going to bed with a severe chill, followed by fever. Before rising the next morning there was sudden very severe general abdominal pain. Tympany and great general tenderness followed, with wiry pulse, dry tongue, and other signs of acute peritonitis. After a week of treatment, mainly by opium, at the hands of her physician, the woman was sent to the medical wards of the Methodist Hospital under the charge of Dr. J. H. Lloyd, who asked me to see her. It was now about two weeks since her illness began and one week since the pain started. The temperature was not irregular, and ranged from 101° to 102°. The eyes were abnormally bright; the cheeks flushed, the mind very clear; the abdomen universally tender and much distended. No tumor was discoverable. There were no signs of extra-uterine pregnancy. The uterus was small and moderately fixed, the vaginal fornices somewhat resistant, as though loose clot occupied the peritoneal cavity. Rectal examination showed a general fulness behind the uterus, but nothing suggesting a sac or tumor. At this time there was doubtful dulness in the flanks, which could not be confirmed later.

Pain and temperature improved slightly for two weeks, but the woman lost flesh. At the end of that time, four weeks after the onset, fluid could for the first time be positively demonstrated lying high up on the left side. The vaginal vault was now hard, and nothing could be determined from below. The fluid rapidly accumulated during the following week, distending the left side of the abdomen to the ribs; the pulse, temperature, and general appearance of the patient suggested the presence of pus, and she was now placed entirely in my charge. Operation six weeks after the onset of the disease revealed the following remarkable condition: The entire peritoneal cavity was lined by smooth, purplish, easily bleeding false membrane, and contained four pints of yellow, thin pus, with several ounces of pultaceous, yellow masses of purulent lymph resembling omelet in appearance. These masses were easily broken up, but ran out of the wound in irregular lumps many of which would have filled a tablespoon.

No intestines were to be seen; they were completely collapsed and occupied the hollows on either side of the spine in the upper abdomen and the region just over the insertion of the mesentery below, being completely covered by the single smooth sheet of false membrane. The hand was passed into the abdomen and the whole abdomen explored from the diaphragm to the bottom of Douglas' sac for granular surfaces of tuberculosis or for thickening or enlargement, to indicate the origin of the disease, but without result. The kidneys could not be separately outlined, being covered by collapsed intestine, but inasmuch as everything in the abdomen hugged the spine and posterior wall very closely, any enlargement would have been detected.

The region of the appendix yielded no light, though carefully explored. The ovaries, tubes, and uterus were free behind and easily outlined, as they lay plastered forward against the base of the bladder. The hand could be passed to the bottom of Douglas' sac and over the sacral surfaces. The slightest manipulation caused oozing of the surfaces of the peritoneum, which appeared greatly thickened, but contained no millet-seed nodules and showed no adhesions. A thorough toilet of the cavity was made, many gallons of hot, filtered, and boiled water being passed through, the fingers carefully dislodging lymph. Glass drainage was used, followed by a gradually shortened rubber tube, for five weeks. The discharge from the tube, while it contained some pus, was never offensive. The wound, being carefully washed with hydrogen dioxid frequently, healed rapidly. In the third week, after carefully sterilizing the glass drainage-tube to prevent inoculation with superficial discharges, eight ounces of warm Thiersch's solution were on each of two occasions allowed to flow into the abdomen under eighteen inches of hydrostatic pressure. This failed to dislodge any pus and returned quite clear, so the washing was not repeated. The patient improved very rapidly; put on many pounds of flesh; is without pain or tenderness, and the site of the drainage-tube is closed. Seven months after the operation she reported herself as well.

Through the courtesy of Dr. Riesman cultures were made for tubercle-bacilli from the pus obtained, but without result. A careful examination of a piece of the thickened parietal peritoneum removed at the edge of the abdominal wound also failed to show tubercle-bacilli. I am assured, however, by a pathologist that this evidence is not conclusive of the non-tuberculous character of the process. My own impression is that the origin was tuberculous, possibly in a kidney; that the fluid originally was ascitic and that it became purulent

shortly before the operation. Negatively, I know of no case of universal purulent peritonitis of long standing in which the patient has recovered if the source of the pus was due to ordinary infection, as from the bacterium coli commune or the staphylococcus pyogenes aureus. The relation to the kidney is suggested by the fact that during convalescence pus without casts has at times appeared in the patient's urine, and by the fact that she has stated that she long has given up the wearing of corsets because pressure over the region of the right kidney in the flank caused occasional discomfort. At all events, she now looks and feels well.

The following case is the only one in my experience in which perfectly normal tubes and ovaries have been removed except for fibroid tumor. The object was the cure of well-marked epilepsy of decided menstrual type. The patient remains well physically, but the improvement in the epilepsy was only temporary, and now, three years later, her condition is even worse. The case deserves to go on record as a failure, and serves still further to confirm the opinion now held by most neurologists, that in true epilepsy no permanent benefit is to be derived from an artificial menopause if no disease of the reproductive organs exists. This opinion was held at the time of operation; but three years' previous observation, and a record of every attack for one and a half years, showed the truth of the patient's statement that the epileptic attacks grouped themselves about her periods, had begun at puberty, and had been absent for two or three months at a time when her periods chanced to be absent. She was also confirmed in self-abuse, was not to be trusted with unscrupulous men, and her mind was becoming dull. She had for three years been confined in a home for incurables. The operation was the earnest desire of herself and friends, but was refused until a long trial of medical treatment proved of no avail in improving her condition.

These statements are made because I feel that operations upon the normal genitalia call for very distinct justification in each case. The history was as follows:

Case III. *Epilepsy; oöphorectomy; no improvement after three years.*—E. B., aged thirty-two years, was an epileptic from puberty at thirteen years. Her periods recurred every four weeks, and lasted from four to six days; the quantity was normal; pain was moderate. Usually from four to ten convulsions occurred just before or during the flow, with *none in the intervals.* An aura was felt from the umbilicus to the head; the tongue was bitten; the shoulder was dislocated several times; total unconsciousness occurred, followed by sleep or stupor. During sixteen years there were at least three occasions when the menses were absent two or three months, when no convulsions occurred during the same interval. Indiscretions in diet would bring on attacks, but almost never except near a period. Examination revealed no pelvic disease; the labia minora were unusually large. Though not considered very hopeful, after long treatment by other measures and consultation with several physicians, total removal of the adnexa was performed in June, 1891. Aseptic recovery took place. No menses have been observed since. For a year the convulsions were lessened in severity and frequency; but now, after three years, the woman is rather worse if anything. Her mind has continued to degenerate, and she has prolonged periods of hebetude. The effect on the self-abuse has not been learned.

Case IV. *Cirrhosis of left ovary; extreme pain; oöphorectomy; great improvement, lasting three years.*—E. T., aged fifty-two years, unmarried, was blind from childhood. A malignant tumor was removed from the right breast and axilla eight years previously by another surgeon. For four years prior to the celiotomy she had intense paroxysms of pain in the left ovarian region, almost daily, causing her to roll about the bed and moan or scream for hours. As other drugs failed, the morphin-habit was gradually acquired, and at the time of the operation her allowance was three grains daily. The pain was genuine and was much influenced by the approach of storms. After being under treatment with other measures for one year, celiotomy was performed. The left ovary was found to be exceedingly small, of the size of two white beans and very hard, though not calcified. It was removed, and there was uncomplicated recovery from the operation. No morphin was given from that date. The pain was very greatly relieved, and though the patient's surroundings remained the same, there was much improvement in weight and appearance. Now, three years later, attacks of pain are at times absent for months and are of mild character. The patient has never failed at every interview to express earnestly her gratitude for the operation and the relief it brought. She was seen well four days ago.

This case is unusual in that the operation was performed for *pain.* This is a deceptive indication, and very rarely by itself justifies abdominal operation.

Next follows an instance in which a pyosalpinx would partially empty itself at times, but for seventeen years made the patient an invalid; complete cure was brought about by operation, lasting four years to date.

Case V. *Pyosalpinx.*—J. D., aged thirty years, menstruated just once at twelve years, when she immediately became illegitimately pregnant and acquired gonorrhea. She bore a child that is still living, but had an extremely difficult labor, complicated by pelvic inflammation and mammary abscess. She has never had good health since, *i. e.*, for seventeen years. There is always pain in the left side, and also attacks of bladder-derangement, with abdominal pain and soreness, which confine her to bed for weeks. Six years ago she was in bed nine weeks with pelvic inflammation, when there was a sudden gush of ill-smelling discharge. She is now just able to be out of bed, but at times severe paroxysms of pain in the abdomen make it impossible to straighten the body for hours. When operated upon she had been in bed about three months with symptoms of pelvic peritonitis. Examination showed a tense, very tender fluid mass to the left of the uterus and bulging into the rectum. A few days later there was a discharge of several ounces of horribly offensive fluid from the vagina, aptly described by the patient as like "old rotten egg that is red." Two days later the menses appeared. This discharge gave much relief, but as her years of invalidism had continued after previous discharges, celiotomy was performed, and with the greatest difficulty two tubal and ovarian masses, riddled with pus-pockets, were completely removed. Flushing and glass-drainage were employed; and excellent recovery followed. For this

woman life began anew. For the first time in years she was without pain. There was rapid increase in weight, and for four years she has worked hard six days of every week, never ceasing to be grateful to the operator.

CASE VI. *Retroversion with descent; torn sphincter; anterior fixation of uterus.*—Mrs. B. (sent by Dr. M. K. Elmer, of Bridgeton, N. J.), aged twenty-nine years, had three children. Her sphincter was torn in labor two years ago, and she had no control of her bowels. Two attempts at repair at good hands in one of our large college-hospitals have greatly discouraged the patient by their failure. Complete success was obtained by a curved incision in front of the anus from one end of the torn sphincter to the other. The ends of the muscle were picked up by a strong catgut suture in a curved needle, and were brought together in front of the anus. The catgut was buried, and reinforcing wormgut sutures were *introduced afterward*. The result was permanent, and absolute control remains.

She had also adherent retroversion with salpingo-ovaritis, considered to be of a grade sufficient to render useless further attempts at cure without celiotomy. The uterus was stitched to the abdominal wall with silk. Twelve months later she reports great benefit from this operation, and freedom from pain, though obliged to do housework and nursing.

CASE VII.—The interest in this case lies in the opportunity that it afforded to examine from within the abdomen an inguinal ring upon which an operation had been done for hernia ten years before. Dr. John Ashhurst had operated for strangulation. Though I am unable to learn that any special effort was made to obtain a radical cure, the hernia never recurred. Aside from the pelvic condition of an adherent, prolapsed, sacculated tube containing inspissated and hardened inflammatory material, for which I performed celiotomy, the patient complained of pain at the site of the old rupture when standing. The inguinal canal was found to be closed at the internal ring, but a diverticulum of peritoneum not more than an eighth of an inch in depth passed behind the internal pillar of the ring, and without doubt served to nip a portion of intruding bowel. The resulting pain was afterward largely controlled by a truss.

At the time of the celiotomy the woman presented the usual picture of chronic invalidism, with mingled neurotic and objective symptoms of old pelvic disease. Several months of previous treatment in the hands of her physician, Dr. M. K. Elmer, and in my own at the Methodist Hospital, yielded little result. The diseased tube and ovary on the left side were finally removed. Buried silkworm-gut sutures were introduced into the abdominal wound. She made an aseptic recovery, and reports, nine months later, great improvement in general health and strength, and no pain except at the site of the old inguinal hernia. She has been married eleven years, but is sterile.

CASE VIII. *Tuberculosis of peritoneum; prolonged drainage without cure of disease.*—This patient came under my care, at the Presbyterian Hospital, for enormous ascites in August, 1892. She was forty-eight years old, unmarried, and had a tuberculous family history, the mother and sister presenting pulmonary tuberculosis, and nine brothers and sisters dying in infancy. Her illness began four months previously as a painless swelling of the abdomen, which had rapidly increased until the limit of distention had apparently been reached. She was emaciated, with a small pulse of 150, the stomach rejecting all but the smallest quantities of peptonized liquids. Vaginal examination without ether being impossible, rectal examination disclosed no apparent tumor, but a fixed uterus and small roughened masses on both sides. The extreme distention called for immediate relief. Celiotomy showed a condition of the visceral peritoneum which was considered at the time to be tuberculous, though the parietal peritoneum accessible for removal and examination was smooth and showed simply increased vascularity. The small intestine generally was hardened, stiffened, and contracted, its loops slightly adherent, except in the left half of the pelvis, where they were matted about a small, resonant enlargement which appeared like a portion of the descending colon. There was no tumor at this time. The adhesions were rough, from a vast number of minute granules. The peritoneum over the small intestines in the left side of the pelvis was red and covered with minute elevations like granulation-tissue. The ovaries and tubes were buried in rough, cheesy adhesions.

The desperate condition of the patient precluded any attempt to separate and clear up the small mass of intestines, and drainage alone was given a chance at cure. Two months and a half later the fluid had again accumulated, and a second celiotomy was done with the object of removing any nidus of disease in the left side, and possibly resecting the colon. On removing the fluid, however, large new-growths were found choking the pelvis and absolutely sessile upon the anterior abdominal wall four inches above the pubis. A nodule, as large as a small egg, was seated on the wall above the umbilicus, and many were scattered through the omentum and mesentery. The operation was evidently hopeless, and the abdomen was again closed, and drainage provided for. The incision gave rise to no difficulty, and the patient continued fairly comfortable for about twelve months, being occasionally relieved of the ascites by aspiration, the quantity obtained varying from eight to fourteen pints. Emaciation was extreme, but there was no pain as from malignant disease. The woman died of facial erysipelas, seventeen months after the first operation and fourteen months after the second. The autopsy was performed by Dr. H. W. Cattell, who considered the large masses, adherent to the uterus, tubes, ovaries, and intestines, together with a cyst unknown origin containing several pints of fluid, to be tuberculous. The specimen was shown by a resident physician, Dr. Swan, at the Pathological Society, and unfortunately lost, though referred to a special committee for examination.

The prolonged drainage of tuberculous disease of the abdomen is only curative when the disease does not involve the parenchyma of organs and is confined to the peritoneum. One such case under my own observation is apparently entirely well five and a half years after drainage by celiotomy.[1]

Radical operative treatment is demanded in some cases because the hernial sac is largely buried in the superficial fat, and a belt or truss has no chance to

[1] Trans. Philadelphia County Medical Society, 1894.

reach the orifice of exit through the fascia and muscles. In the following case, in a laboring-woman, mechanical retention of the hernia was impossible.

CASE IX. *Umbilical hernia in the obese.*—Mrs. C. was subject to attacks of pain and nausea from an umbilical hernia of spontaneous origin. The tumor was largely made up of irreducible omentum, and was contained in a very irregular sac, with numerous prolongations into the abdominal fat. The patient was very short and exceedingly obese. The adherent omentum was tied off and removed. The sac was dissected out completely, and the deep fascia and muscles were united by buried silkworm-gut sutures, four to the inch, and these were allowed to remain permanently. The skin and superficial fat were separately sutured. The woman made an uncomplicated operation-recovery, the wound being aseptic. Six months later the hernia had not recurred.

CASE X. *Adhesion of small intestine following celiotomy.*—M. D., twenty-six years, had both tubes and ovaries removed by a well-known operator one year before coming under observation. She had since been in different hospitals and in a home for convalescents, complaining of abdominal pain. This pain frequently caused nausea and vomiting, always preceded a stool, and was excited by the movement of intestinal gas. It was frequently referred to the umbilicus, and was considered to be of intestinal origin. Celiotomy in the Trendelenburg position disclosed two points of adhesion of the small intestine, one near the old incision, the other to an ovarian and tubal stump. The latter was freed with the scissors, and the bowel-wall stitched with silk, aseptic recovery following, though there was some vomiting late in the convalescence. One year later the patient was seen and declared herself cured. She had had no more pain, and had been working instead of leading the life of a hospital-inmate as before. Post-operative adhesions are best prevented by clean surgery and by the avoidance of constipation afterward.

RESECTION OF THE ANKLE-JOINT, WITH REMOVAL OF THE OS CALCIS, FOR ACUTE OSTEOMYELITIS.

BY H. L. JENCKES, M.D.,
OF GALENA, ILL.;
MEMBER OF THE AMERICAN MEDICAL ASSOCIATION.

CASES of acute suppurative periostitis, or osteomyelitis are of so frequent occurrence as to attract no special attention. While in many cases the etiology is obscure, in some it is undoubtedly tuberculous. Clinicians have not been slow in recognizing the gravity of the affection, although it is comparatively recent that inflammation in bone has been treated like suppurative inflammations in the softer tissues, *i. e.*, by free incision.

The diagnosis of inflammation in bone is not always easy, some forms pursuing a slow course, and, giving rise to but little pain, are thus not diagnosticated until the cold abscesses which they cause appear.

As the result of osteomyelitis, the tibia and femur are seen to increase in size and to attain an enormous thickness. Such was the condition of a tibia from which I recently chiselled away part of the bone and removed sequestra.

The case of osteomyelitis considered in this report occurred in a child about seven years of age. The family at first thought him suffering from rheumatism of the ankle-joint, and for this supposed condition medicine was obtained, which afforded little if any relief.

When I first saw the case the joint was greatly swollen and inflamed. Pus had formed, and would soon have escaped spontaneously. Recognizing the serious nature of the disease a free incision was made into the affected parts, and nearly a teaspoonful of pus evacuated. Directions to have the ankle frequently washed with mild antiseptics were given, but were only imperfectly carried out.

At the end of a week the family was led to believe the child improving because he was suffering less pain, but upon examining the joint, at the end of another week, it was found to be in a far worse condition than when first seen. Several sinuses had now opened, and through these denuded bone could be felt. A sinus on the dorsum of the foot led down to the astragalus, from which a small piece of bone had exfoliated. This was removed. Several openings under the outer malleolus led to the calcaneum, from which the periosteum had separated.

As resection of the joint and removal of the dead bone offered the only prospect of saving the foot, this was done. The disease being confined chiefly to the calcaneo-astragaloid articulation, and involving the calcaneum mainly, I decided to remove that bone. For this purpose the patient was anesthetized with ether. An incision was made through the sinuses on the outer aspect of the foot, and carried from the calcaneo-cuboid articulation backward through the tendo Achillis. Through this incision the bone was grasped and removed. The sinuses leading down to the astragalus were now enlarged, and that bone was scraped and cleansed. The wounded surfaces were irrigated and dusted with iodoform. The subsequent course was favorable throughout. The wound healed firmly by granulations, and a useful foot was the result.

In separating the attachments of the calcaneum the operator should avoid wounding the posterior tibial artery. The vessel is here situated midway between the inner malleolus and the tuberosity of the os calcis.

MEDICAL PROGRESS.

Operative Treatment of Old Dislocations of the Hip.—HARRIS (*Annals of Surgery*, vol. xx, No. 3, p. 319) has reported the case of a ranchman, thirty-three years old, who, while threshing, was struck on the left hip by an iron pulley weighing about 350 pounds. The injury was so severe that the man was unable to use the leg, but he supposed that the injury was only a severe sprain, and that recovery would speedily ensue spontaneously. After walking around on crutches for about a month without improvement, he consulted a physician, who diagnosticated a dorsal dislocation of the left hip. The man was anesthetized and reduction attempted, but without success. Four days later a second attempt at reduction was made, and this was likewise unsuccessful. The man remained in bed for two days, and then got up and went around on crutches again. Two weeks

later a third attempt at reduction was made, and again without success. The man was unable to use the leg at all, and could only get about with the aid of crutches. The leg presented the usual characteristics of dorsal dislocation: slight flexion, adduction, internal rotation, and shortening, with the top of the trochanter above Nélaton's line. The whole limb was somewhat atrophied, and both active and passive motion were much limited and painful. It was now determined to cut down upon the joint. Accordingly, nearly four months after the injury, an incision about 14 cm. long was made in front of the great trochanter, between the tensor vaginæ femoris and the gluteus medius, leading directly down to the acetabulum and anterior surface of the head and neck of the femur. The acetabulum was found filled with a tough, adherent, connective-tissue proliferation from the anterior portion of the capsular ligament, which in falling over the cavity completely closed it. On cutting through the capsular ligament the head of the bone was found resting on the posterior and superior edge of the acetabulum in a shallow depression, the lining of which had a smooth, cartilaginous feel. Immediately in front of the head and helping to fill the cotyloid cavity was a piece of bone, curved in shape, about 3 cm. long by 1 cm. deep and 0.5 cm. wide, which had been detached from the posterior wall of the acetabulum, and which may have been an obstacle to early reduction. The head of the bone was still covered with smooth cartilage, while the neck had acquired new firm adhesion to all of the surrounding parts, thus producing a new capsular ligament. A restoration of the ligamentum teres could not be demonstrated, but a small portion of it was present in the depression in the head of the bone when this was turned out of its new joint. The adhesions of the neck were divided, and all the muscular attachments to the great trochanter and shaft as far down as the lesser trochanter were separated subperiosteally from the bone, thus liberating the entire upper end of the femur. By means of the gouge and sharp spoon the acetabulum was freed of capsular ligament and new connective-tissue formation. The cartilage lining the bottom of the cavity was found to be still smooth. The head of the bone could not, however, be made to enter the acetabulum, which seemed too small. The cavity was consequently enlarged somewhat posteriorly with the gouge and mallet, after which by considerable exertion and manipulation, the head was finally returned to its place and the leg assumed its normal position. The wound was partly stitched up, and the remainder packed with iodoform-gauze. The limb was placed in the extended position, slightly abducted, and externally rotated, a plaster cast put on and extension applied. The operation occupied two hours, and the patient suffered considerable shock, although the loss of blood was not large. Reaction took place promptly, and the progress of the case was favorable from the onset. There was considerable serous discharge from the wound during the first few days, necessitating rather frequent renewals of the dressings. In three weeks the wound was closed, but in another week there was a rise in temperature, with pain over the great trochanter. Upon opening one corner of the wound a small quantity of sero-pus was evacuated from a small cavity superficially situated over the trochanter and not communicating with the joint. This was drained by a counter-opening posteriorly, and it gave no further trouble. The extension was continued for three weeks. After its removal the leg swelled a good deal throughout its entire length. This swelling was relieved by tight bandaging, so that in about two weeks more, or six weeks from the time of the operation, the man was permitted to get up on crutches. In three months he could walk with a cane without pain in the hip. There was active motion in all directions.

As a result of this experience and from a study of the literature the conclusions are reached (1) that owing to the danger of fracturing the neck of the femur, of laceration of the great vessels of the thigh, of shock, and death, the application of great force to reduce old dislocations of the hip should be discontinued in favor of arthrotomy; (2) that subcutaneous operations in cases of old dislocation are without benefit; (3) that osteotomy below the trochanter can scarcely come into consideration at this day; (4) that resection is only to be thought of when reduction by arthrotomy fails; and (5) that the operation which has given the best results is free arthrotomy, with reduction after the method pursued in the case here reported.

Successful Suture of Perforated Gastric Ulcer.—BENNETT (*Lancet*, No. 3697, p. 21) has reported the case of a woman, forty-one years old, who while walking up stairs felt a sudden, violent pain in the region of the umbilicus, became faint and fell to the ground. Collapse developed, the temperature becoming subnormal and the pulse small. The abdomen was slightly distended. Above the level of the umbilicus there was acute pain and tenderness; the normal hepatic dulness was replaced by tympanitic resonance. Abdominal respiration was restricted, but not entirely absent. There was no general peritonitis. The expression of the face was typically "abdominal." There was neither vomiting nor nausea. For two years the patient had suffered with constant flatulence, much increased by food. There had never been acute pain, vomiting, nausea, or hematemesis. For two weeks there had been a little "nagging" pain around the umbilicus, which was greatly intensified at a spot an inch above and rather to the right of the median line after taking solid food. On the whole, however, the woman had considered herself in fair health until the occurrence that brought her under observation. She came of a tuberculous family, and on three occasions had had inflammation of the lungs. The signs of perforation of the stomach appearing sufficiently distinct, immediate operation was determined upon. The abdomen was opened by an incision in the median line, extending upward for about three inches from a point just above the umbilicus. A gush of opaque fluid followed the opening of the peritoneal cavity. The exposed surface of the liver was clothed with recent lymph, and the parts about the pyloric region of the stomach were somewhat matted together by fresh adhesions. Careful exploration of the anterior aspect of the stomach having failed to detect any lesion, the abdominal wound was enlarged for another inch and the stomach drawn out and turned upward. There was then found on its posterior surface, about two and one-half inches from the pylorus, a perforation equal in size

to a No. 6 English catheter, surrounded by an area of gristly induration about two inches in diameter, which, diminishing at the edges, finally faded away into the surrounding healthy parts. The extreme right margin of this induration nearly touched the pylorus itself. The small perforation was just made water-tight by a suture including the whole thickness of the walls of the stomach except the mucous edge. The peritoneum on each side of the perforation, greatly thickened and stiff was then brought across by six Lembert sutures, so as to completely cover in the occluded perforation. Another series of sutures, to act as a stay, to reduce the tension on those already introduced, was placed at each end in the long axis of the stomach, extending well into healthy peritoneum. These sutures at the hepatic end passed on to the pylorus. The parts having been gently wiped over with a soft sponge, were returned to the abdomen; the abdominal wound was brought together with silkworm-gut and dressed in the ordinary way. No irrigation was practised and no drainage-tube was used. For four days rectal feeding was practised, plain water being allowed to be taken by the mouth *ad libitum* in small quantities at a time. Two weeks after the operation solid food was being taken in the usual way with relish and comfort. The abdominal sutures were removed on the seventh day. Seven weeks after the operation the patient was dismissed, feeling well and gaining flesh. There was no pain of any kind; the old symptoms of flatulence had entirely gone and showed no sign of recurrence, although the woman had been taking ordinary hospital-food for nearly a week.

Traumatic Rupture of the Jejunum without External Lesion.—WHITE (*British Medical Journal*, No. 1742, p. 1077) has reported the case of a miner, seventeen years old, who had been crushed in the pit and presented a collapsed condition, the pulse at the wrist being almost imperceptible. He lay with the knees drawn up and complained of severe abdominal pain. The abdomen was rigid and board-like, but presented no bruise. The tenderness and rigidity were most marked in the left umbilical and lumbar regions. There was an absence of abdominal respiration and no dulness could be detected. Collapse increased and vomiting of gastric and bilious matters set in. A day after the accident the man passed a normal stool and immediately thereafter died. Upon post-mortem examination no evidence whatever of external injury was discoverable. On opening the abdomen the intestines were found covered with a fibrinous exudation, on removal of which the vessels were seen to be much injected. Just to the left of the spine the small intestine was ruptured at about the middle of the jejunum. The rupture was transverse and involved the whole of the circumference of the bowel with the exception of about one-eighth of an inch at the attachment of the mesentery, which latter was slightly bruised. The bowel itself was only crushed for a distance of about a quarter of an inch on each side of the rent, the edges of which were thickened and edematous. Only about a dram of blood escaped, but the contents of the intestine were extravasated. The other organs were healthy, with the exception of some enlargement of the mesenteric glands and some old pleuritic adhesions. It was learned that the lad had been crushed between a wagon and a prop in such a way that a broad, flat surface was applied dorsally and a moderately sharp ledge anteriorly. The rupture probably occurred from compression of a moderately full coil of intestine between the ledge and the spine.

Post-pneumonic Thyroiditis due to Pneumonia cocci.—LION and BENSAUDE (*Bull. de la Soc. Anat. de Paris*, June, 1894, p. 434) have reported the case of a man, forty-nine years old, previously healthy and without personal or hereditary predisposition, in whom developed a frank attack of pneumonia of rather protracted duration, defervescence taking place slowly, and not being complete before the seventeenth day of the disease. During the week following, the appetite returned and the general condition improved, but on three occasions the temperature reached 100.4°. A day later the patient complained of pain in the neck, and it was observed that there was also swelling and tenderness. The temperature was now found to be 102.9°. Treatment with inunctions of mercurial and belladonna ointment was for a time employed, but in the course of a few days an abscess formed in the left lobe of the thyroid gland, which, after the demonstration by exploratory puncture of the presence of pus containing pneumonia-cocci in pure culture, it became necessary to evacuate.

THERAPEUTIC NOTES.

Cactus Grandiflorus.—SHARP (*The Practitioner*, No. 315, vol. liii, No. 3, p. 160) thus summarizes the salient points of an essay upon *Cactus grandiflorus*:

The literature of *Cactus grandiflorus* is comparatively extensive, but vague, too many properties being ascribed to the drug, and upon too slender evidence, there being no authoritative evidence of a pharmacologic or carefully carried out therapeutic kind. The chemistry is as yet unknown, authorities on this subject not even mentioning the presence of a glucoside or alkaloid; and, so far as can be made out after extensive trials, neither of these bodies could be obtained. The most important agents appear to be a series of resins. The pharmacology is necessarily indefinite, one having to work with rather insoluble resins. These cause contraction of the bloodvessels of a frog, but this is not in the nature of a digitalis-contraction, but is believed to depend on simple acidity. On the heart of the frog the resins have little or no effect, comparisons being made with digitalis in the same animal. The drug itself would appear to be pharmacologically inert, and there is no proof that it shortens diastole, nor in fact that it has any special action on the heart-muscle at all. Therapeutically, *Cactus grandiflorus* cannot be included in our list of cardiac drugs. It is not even a simple stomachic tonic, and, at most, all one can say is that it has some slight diuretic action.

Resorcin for Whooping-cough.—BEDELL (*Indian Medical Record*, vol. vii, No. 3, p. 76) reports four cases of whooping-cough successfully treated by topical applications, twice daily, of a solution of resorcin, one dram to the pint.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

THE PHYSICIAN'S VACATION.

THERE are a number of reasons why the summer vacation must be planned long in advance, and just as many why we should keep well in mind the benefits to be derived from it when properly carried out.

More than in any other profession or calling, the physician, in duty to himself and to his patient, is bound to take a season of rest at least once a year. Like the old-time housewife, his work is never done. If patients do not demand his attention for from sixteen to twenty hours of the twenty-four, he, as none other, is compelled to seize every possible moment for the study of the progress of his science. The result is that in the year he gives, as a rule, far more hours of labor to his work than do other members of the community. The argument for a rest, therefore, is based upon physical, mental, and moral grounds. One reason that we fear will not have quite the general acceptance it deserves is the help given to the younger colleague, who temporarily takes charge of the practice of the elder.

It is growing more common for city physicians to take a summer vacation; but it is not so generally felt that the physician of the village and country should do the same. Yet none can need it more, and there are in his case especial reasons for the practice. It has long been recognized that life in the country is likely to lead to monotony and unprogressiveness. The friction of minds in the cities, and mutual ambitions and rivalries, not to say jealousies, keep mental and professional energy at a high pitch. Country physicians might, therefore, with much advantage, utilize the season of rest and change to form acquaintances and to learn by word of mouth of the work and worth of their distant colleagues. It would be a double benefit if we could have short summer post-graduate special courses of medical study at mountain or seaside resorts, such as the Summer School at Dartmouth, and the Biological School at Wood's Hall, Mass.

Medical congresses should be held at such places, and if, as is too common, they were not rushed through in such stupid and silly haste, they might become the means of greater good to greater numbers than is the case at present. It seems to be a growing feeling that the sooner a program can be got through with the better, and we have lately attended meetings where members were wheedled and bullied into reading papers by title or in abstract, and in which discussion was shut off, as if the object of the meeting was to open and adjourn like a Jack-in-the-box machine. It is undoubtedly true that, as at present carried on, the good of medical meetings is far more social than scientific. It is, perhaps, true that most medical congresses will continue to result chiefly in that sort of good; but it is certainly not necessary that the distinctively medical side be utterly extinguished in favor of the social.

While awaiting the summer medical school, where should the physician spend his resting season, how long should he stay away, and what should he do?

It goes without saying, that each will answer these questions differently for himself. We only urge that, in view of the modern ease of intercommunication, everyone go far from home—as far, we were about to say, as possible—and remain away as long as he can. If foreign travel is possible (and it is generally more feasible than one at first thinks), by all odds undertake it. Perhaps a little travel, like a little knowledge, may be "a dangerous thing," and one may return to his old habits without the proper lessons learned or the improper conceit unlearned. But it cannot usually fail to broaden the mind somewhat and give us a better opinion of others, to go and visit them in their homes and "see how they do it." Ease of travel has stopped

the formation of languages, dialects, and of patois; it also acts the same way medically. But if not to other countries, at least to other States! Make the change as decided and as distinctive as possible, and, as a rule, it is better to go to a place and stay there—unless, indeed, one travels afoot! Much railway travel in visiting many places is inadvisable.

A physician hardly needs to be advised against seeking the great "resorts" and fashionable hotels. He will naturally seek the company of the hills, the woods, or the seashore, rather than that of people. The advantages of this plan are evident. Nothing so effectually breaks up the monotony and weariness of our laborious life as a temporary leaving of society, the ills and worries of ill people, and a quiet communion with Nature—a peaceful "thinking it all over." Singleness and exclusiveness of duty or work is likely to act injuriously upon the mind. Indeed, every physician should have some absolutely non-medical "hobby." Interest, partial or interrupted, in something wholly different from that pursued as professional is a great preserver of mental and moral hygiene. The vacation-time is, of course, especially adapted to such pursuits. Many, and certainly no fault is to be found with such, will prefer hunting, camp-life, a bicycle-tour, or a tramp over mountain-ranges. Even then the peculiar interests of his profession will not wholly escape him as he mournfully thinks what hygienic evils deforestation and pollution of streams are preparing for those who come after us.

But the world is getting pretty well filled, and society is not entirely to be escaped. In hotels the physician will get his melancholy lesson of how far we are from medical civilization by observing the certainty with which quacks and patent medicines and cure-alls, private and public, are recommended by otherwise sensible people. In some New England village he will, perhaps, find the best minister lauding and working with the drunk-curers, permitting them the use of his church, and signing testimonials of nostrums. He may also hear the confession of the best physician that not to consult with the wretchedest quacks would soon ruin his little and precarious practice. The people still believe in medical magic and miracle-mongering, and that ignorance is a better preparation for the medical man than education.

But, wherever one goes, he will return to his round of duties the better for the rest, and determined to repeat the lesson each year. The mind will have been refreshed and quickened, life will been seen in new lights and by new insights, and the doctor will be better able to meet the demands made upon him by his profession and by his patients. One will do more and better professional work in eleven or ten months, with one or two months of rest, than in twelve without a vacation.

"THE ATTACK ON THE BUSINESS INTERESTS OF THE"—NEW YORK POLICE.

CERTAIN straight-laced, half-bore, narrow-gauge, humpbacked, Pharisaical, and otherwise generally-back-number Miss Nancies, in the city of New York, actuated by malice and envy, and in the hope of damaging the "business interests" of the guardians of the peace of that city, have, as our readers are aware, unwarrantably "attacked the business-methods" of the blue-coated gentlemen in question, and have latterly gone so far in their career of reckless wickedness as actually to prove the truth of their charges. These fanatical New York shriekers should be severely rebuked. It is quite evident—indeed "the logic of circumstances" declares—that their only object is to advance the rival interests of the *New York Herald*. As indisputable proof of this we refer to numerous editorial articles in the *Herald* approving the course of DR. PARKHURST, and refusing to credit the repeated affirmations of the Police Commissioners that he was an impracticable crank.

As a matter of "abstract ethics," it may be wrong to levy blackmail upon gamblers, crooks, and the keepers of disreputable houses; and perhaps a strict stickler for obsolete codes might censure the taking of bribes from "green-goods" operators in return for aid and comfort given to these estimable and enterprising manufacturers in the pursuit of their business. Upon this phase of the question we carefully abstain from expressing any opinion. But, as is well known, abstract ethics should not be applied to practical questions. To do so is to be illiberal, and to show that one does not appreciate the inevitable distinctions between profession and practice, between fine words and coarse actions.

It is true, moreover, that the business enterprises referred to are against the law, and that the police being sworn to obey and uphold the law, their promotion of and participation in illegal practices might seem to the half-bore Pharisees to savor of a betrayal of trust. But such a view is very narrow

and superficial. The laws in question are quite ancient, and we live in a modern era. At the time these statutes were passed there was no Elevated railroad, no Broadway cable, no Bowery tough, no Brooklyn bridge, no boodle alderman, no Riverside drive, no Pantata; and Tammany was in its infancy. The changes incident to the progress of the last —— years, the marvellous advances in arts and sciences, the widespread diffusion of education, and the general increase of political activity render the great metropolis of 1894, with its two million inhabitants, a very different place from the sleepy village of PETER STUYVESANT, or even the large city of the days before the war. It would therefore be manifestly absurd to require of the helmeted and club-wielding legions of the present Commissioners that scrupulous obedience to rule by which CHIEF CONSTABLE HAYS made his stovepipe-hatted force a terror to the law-breaker, a bulwark to the citizen; or to insist upon a literal observance of laws and statutes passed with regard only to the welfare of the peaceful and the law-abiding. Because the Legislature may have failed in its duty and neglected or refused to remove from the statute-book of the Empire State the illiberal legislation of a past age, the Police Captains should not therefore be hindered in their endeavors to promote the era of fraternity and good-will, without regard to artificial class-distinctions.

If one citizen chooses to be a merchant, another to be a banker, and another to be a confidence-man, why is not the last named as much entitled to police protection as the other two? This is a land of freedom and equal rights! And if the confidence-man chooses to pay the police officer for favors rendered, whose affair is it but theirs? And why should not the merchant and the banker, the fruit-peddler and the unfortunate woman, likewise contribute their proper proportion of extra-judicial taxes for the support of the finest police force in the world? The captains and inspectors and wardmen must do their duty regardless alike of the failures of the Legislature and the imperfections of the statute, and if the restrictive law is not repealed, what course is open to them except to violate it?

But there is still another consideration even more potent than those just urged. As an esteemed contemporary has conclusively proved[1]—questions of right and wrong are not so simple as the unsophisticated may imagine. It all depends upon the point of view. Morality is one thing and "business" is another. Morality might condemn the assistance rendered to the green-goods dealers: but business—never! Well, hardly ever. That is, it might be very wrong if it were not well paid for. This fact of payment, as our readers will observe, our contemporary properly insists upon as the crucial distinction. What might be a question for the ethical student, so long as no remuneration passes, becomes purely a matter of business, so soon as pecuniary considerations are involved. Now, the police have not been charged with helping the verdant-stuff merchants *for nothing*. On the contrary, it is admitted by the narrow-gauge Miss Nancies that the officers concerned receive a sum certainly no less than the celebrated fund of *eight thousand dollars per annum* which our contemporary has on a previous occasion referred to. To ask them to forego this revenue for a mere matter of "abstract ethics" would certainly be very unbusinesslike.

If the humpbacked reformers in New York really wish to suppress the green-goods traffic they must adopt a different plan. They must not try to prevent the dealers' circulars and telegrams from being handled by the Post-office, or the places of meeting from being guarded against the Federal authorities by the local police. It is evident that the people want these things or the circulars wouldn't be issued or the meeting-places maintained. If the demand were cut off the trade would cease to be profitable, and would therefore be discontinued. Now the way to cut off the demand is *to educate* the people. As is well-known, honesty and education are synonyms; witness the Keystone Bank, the Panama Canal, etc., etc. Educate the people, and in a million years or so the green-goods traffic will die a natural death. Meanwhile we should severely frown upon the miserable attempt, solely undertaken for the benefit of the *New York Herald*, to injure the business interests of the New York police.

[1] "The right or wrong of many things depends upon the standpoint from which they are viewed. It makes quite a difference whether one views Chicago from the top of the Auditorium or from the Chicago River. Advertisements present a different aspect to one who looks upon them from a purely business standpoint than they do to the ethical student."

"It is not good surgery to put a plaster over a pus-discharging sore, even though this were effective in preventing the pus from being seen by the patient or his friends. Good surgery cuts down, finds the origin of the pus, and removes the dead bone, granulation-tissue, tumor, etc., which produces the pus. So with the whole list of objectionable advertisements in medical journals. Let us go to their sources and remove these. Create such a professional life as will render these advertisements unprofitable, and the disease will be cured. All else is simply an unscientific method of operation."

EDITORIAL COMMENTS.

The Priority Executioner.—The history of science is filled with records of the discovery of some truth by two or more minds independently of each other. Thus, to take two illustrations known of all, Wallace and Darwin, each without the knowledge of the other's work, discovered the biologic law that now passes under the name of Darwinism, and Helmholtz and Mayer enunciated the doctrine of the conservation of force in the same way. Wise men delight to honor the memory of Wallace and of Helmholtz for the *originality* of the discoveries, and give only a little more honor to the men who first put them on record. Good men also delight in the calm dignity of the *later* discoverer who gladly joined in the award of *priority* to the *earlier* rival. How fatuous would have been the addleheadedness of the later discoverer if he had quarrelled with the verdict and ceaselessly vaunted his own honor!

But there is yet another possibility—the much-protesting third person who himself has discovered nothing, and who devotes his energies to croaking and pooh-poohing and preaching that no other fellow did discover anything. The burden of his lamentation is that there is nothing new under the sun, and least of all is this particular thing new. Moreover, if it were new it is not true. "Go to; let us show up this fraud," is his ever-renewed text. This is the priority-executioner, a species of literary protestant who adds much to the pleasure of the readers of medical and other journals One wonders, in reading his writings, why, if neither new nor true, the matter is considered by him of such importance as to arouse his criticism, and if to nobody else is due the honor, why he is so anxious that this nobody shall have it. One's amused interest is also heightened by noting that the worthless new thing had been used by the critic before and ever since the silly would-be-discoverer was in his swaddling-clothes. One more than suspects the motive of the priority-killer is not quite purely impersonal or genuinely scientific. Lameness of logic and over-much protestation seem to lead to the conclusion. But when the silly would-be-discoverer does not care a blue bean whether he made his "discovery" first or not first, caring only if there be anything in it of use to the world, then are the exorcisms of the paralyzer most vain and his gesticulations painfully ludicrous.

The Abuse of the Reprint.—It is a courteous and commendable custom for an author who has written an article of real value to send reprints thereof to libraries for reference, to his friends for preservation, and to those pursuing the same line of investigation, who might not otherwise become so soon acquainted with his researches. When, however, the reprint is used merely to advertise the fact that the writer is peculiarly skilful in a certain specialty it is less commendable; and when it is used to advertise Messrs. Enterprise and Paywell's Panacea, or some similar substance, it becomes anything but commendable. These thoughts are suggested by the receipt of a pamphlet, reprinted from a journal published in a neighboring city, and bearing the title "Functional ———," by X. Y. Z., M.D., Professor of ——— in the ———, etc., which publication although ostensibly coming to us from the author, is quite evidently circulated as an advertisement by, and at the expense of, the firm whose "trade-mark" product is therein recommended (no doubt, honestly) as a sovereign remedy for the affection in question. Apart from all questions of propriety, men who permit their names thus to be misused are very shortsighted. Their advice, however unjustly, comes to be looked upon with suspicion, as not wholly scientific and disinterested; and their reputation becomes upon a par with that of the "advance-agents" of theatrical notorieties—an honorable reputation when one does not pretend to be other than an advance-agent. The advertising-reprint and the reading-notice are twin growths of the same poisonous root, and should be utterly condemned by thinking, self-respecting physicians.

What is the Duty of the State and of Medicine as regards the Congenital Idiot, the Hopelessly Insane, etc., is a question that presses more and more upon our attention. Some two thousand years ago Plato praised the physician who should refuse to lengthen their lives. In a recent paper read before the University Extension Classes at Oxford, England, our esteemed colleague, Dr. Billings, has also asked why we should expend time and money to prolong these lives. Dr. Billings hazards no answer to the question, but its mere asking implies that economically at least there is but one answer. But the economic aspect is by no means the only one. Leaving aside sentiment and religion, we may consider it simply scientifically. The idiot and the insane may be considered as scientific problems. However impossible the solution just now, the presence of these problems, the existence of the beings themselves, keeps before the mind the everlasting interrogation. We would only put the problem out of sight, not answer it, by killing the problem-asker. The inquiry into the etiology would be stopped at once by the *petitio principii* of the premise that the cause of idiocy is indiscoverable. Killing the questioner would be a convenient but somewhat unsatisfactory way of settling a good many bothersome questions. Every effect must have its adequate cause, and the discovery of causes is the duty and work of the scientist, whether physical or medical.

The Greatest Engineering Undertaking of To-day is at once an economic and a sanitary crime. Millions of dollars are being expended to make the Mississippi River a huge open sewer, and to add the filth of a great city to the combined filth of a hundred lesser cities. As each adds its share the water for the use of those further down-stream is more dangerously contaminated and polluted. Economically alone, this waste of nitrogenous compounds is appalling; but, hygienically, what an outrage, not only against future generations, but against the present generation! Vast sums of money are expended to waste a valuable product that could be utilized on the almost limitless prairies about Chicago, and by the waste the health of millions and of a nation is not only imperilled, but certainly harmed. Nothing could speak more eloquently of the need of a strong governmental organization which should legislate upon and control all such undertakings.

The Water-supply of Philadelphia.—As has been frequently shown in these columns, there is but one right way to improve the water-supply of Philadelphia, namely, the plan first advocated by Dr. Henry Leffmann—the erection and maintenance of an adequate filtration-plant. The source is a secondary matter. If filtration shall fail, or if the Delaware and Schuylkill should run dry, the building of aqueducts may be considered. Until such a contingency arises there should be but one question before the municipal authorities, namely, the best and quickest way of building the necessary filtration-basins. We suggest the appointment of a commission of experts selected with the coöperation of the College of Physicians (as the senior medical body of the Commonwealth) to act in conjunction with the Department of Public Works.

American Medical Teaching.—The physicians of America owe an acknowledgment to Prof. Dr. Max Schueller, of Berlin, for his graceful but candid defence of their attainments and teaching methods against the censure of a superficial but not wilfully unjust observer (*Der Aerztliche Praktiker*, August 9, 1894, p. 878). Prof. Schueller points out the vast extent of American territory, the scattered population, the varying conditions, social and climatic, in order to show that no generalization can properly include all American physicians and schools; and, while admitting the defects that American critics themselves animadvert upon, pays a just tribute to the advanced standing of our best colleges and our representative teachers and practising physicians.

REVIEWS.

A MANUAL OF THERAPEUTICS. By A. A. STEVENS, A.M., M.D., Lecturer on Terminology and Instructor in Physical Diagnosis in the University of Pennsylvania; Demonstrator of Pathology in the Woman's Medical College, Philadelphia; Physician to St. Mary's Hospital and to the Southeastern Dispensary; Pathologist to St. Agnes' Hospital. Philadelphia: W. B. Saunders, 1894.

WE regret that we can give this book only faint praise. The author has accomplished his purpose, and perhaps should not be judged by a more exacting standard. But in therapeutics "a little knowledge is a dangerous thing." It is precisely the student who needs an "introduction to the subject" for whom the best and most expository works should be written. This is not such an introduction, but a condensation which can be useful only to those who have least occasion for it.

THE BRISTOL MEDICAL SCHOOL. (Reprinted with additions from the *Bristol Medico-Chirurgical Journal*, 1892, and presented to the members of the British Medical Association visiting Bristol at their Annual Meeting, 1894.) Bristol: J. W. Arrowsmith.

THIS little brochure is chiefly constituted of a record of "The Early History of the Bristol Medical School," from its organization in 1832 up to the formal opening of a new wing of University College in 1892, by Sir Andrew Clark, prepared by Mr. Augustin Prichard, Consulting Surgeon to the Bristol Royal Infirmary. It is neatly illustrated by sketches and photographs, and contains brief biographic notes of the early members of the faculty.

CORRESPONDENCE.

COW-POX (?).

To the Editor of THE MEDICAL NEWS,

SIR: We are just now having an epidemic of a skin-disease that I take to be cow-pox. The initial lesion in every case so far has been on the hands, and with a single exception it has only appeared among milkers. This case occurred in a young miner who handles his mother's cow, though he never milks. The cows in the town have small blebs on their udders, and one or two horses that have been kept in the same stalls with cattle present very suspicious-looking sores.

The first lesion noticed in my cases is a dark-red spot, which in the course of a week becomes purplish, then enlarges to the size of a pea. The skin puffs up until it looks like an inflamed wart; then it slowly fills with lymph and breaks down, leaving a small sore the size of a silver three-cent piece—often smaller than this. About the eighteenth or twentieth day after the appearance of the initial lesion a rash breaks out, looking like urticaria, and covers the hands and face; in one case it covered the chest and thighs, and in another the hands and feet only. The original sore is never painful and never itches, but the rash is both painful and itching; in fact, the patients have to cover with cloths the parts the seat of the rash, to prevent scratching off the skin.

The rash does not become sore, but slowly disappears, leaving no traces of skin-inflammation.

As for treatment, at first not finding any account of this disease in any of my books, I used the usual treatment of skin-inflammations, but knowing the power of menthol to allay itching, I tried it in the following combination, and found it successful, fully controlling the itching—in fact, giving complete relief:

R.—Menthol. . . . . ʒj.
Acid. carbolic. . . . . ʒiss.
Olei olivæ . . . . q. s. fʒiv.—M.
Sig.—Apply to the rash when it itches.

This application shortens the duration of the rash. My first cases lasted about two weeks; since I have been using this combination the usual time is about five days.

Yours very truly,

FRANCIS W. HARRELL,
Surgeon to Seattle Coal and Iron Co.

GILMAN, WASH., August 23, 1894.

THE INTRA-UTERINE APPLICATION OF HYDROGEN DIOXID.

To the Editor of THE MEDICAL NEWS,

SIR: I trust that you will extend a word of caution in regard to the intra-uterine application of hydrogen dioxid after abortion, etc. This matter is again called to my mind after reading the article by Dr. W. D. Jones, page 242 of THE MEDICAL NEWS, of September 1, 1894. The Doctor there states that he "irrigated the uterus with hydrogen dioxid," after having evacuated it in a case of uncontrollable vomiting of pregnancy. How much this may have had to do with the fatal issue I do not

presume to say; but there are undoubtedly two great dangers incurred by such a use of hydrogen dioxid, *i. e.*, the entrance of evolved gas (along with septic fluids if present) into open uterine sinuses, and the entrance into the peritoneal cavity by the Fallopian tubes of the same materials. It is difficult to conceive of a more certain method of producing gaseous venous embolism than by the procedure under consideration, not to speak of the additional dangers of forcing septic material into open bloodvessels and the peritoneal cavity.

Respectfully yours,

A. J. Comstock.

Ventura, Cal.

NEWS ITEMS.

The Southern Surgical and Gynecological Association will hold its seventh annual session at Charleston, November 13, 14, and 15. The meeting promises to be the most successful in the history of the organization. Papers will be presented by the leading surgeons and gynecologists of the South. The medical profession is cordially invited to attend. Dr. Cornelius Kollock, of Cheraw, S. C., is President, and Dr. W. E. B. Davis, of Birmingham, Ala., Secretary.

Dr. Beaven Rake, Government Surgeon and Director of the Leper Hospital at Trinidad, and one of the greatest authorities on leprosy, died on August 24th, from some form of fever, at the age of thirty-six years.

Dr. Jaromir Mundy, a distinguished humanitarian, died at Vienna on August 23d, at the age of seventy-four years.

ORIGINAL ARTICLES.

FORTY CASES OF GUNSHOT WOUNDS.

BY PHILIP MILLS JONES, M.D.,
OF SAN FRANCISCO, CAL.;
LATE SURGEON-GENERAL, ARMY OF HONDURAS, C. A.; ASSISTANT TO THE CHAIR OF OTOLOGY, SAN FRANCISCO POLYCLINIC.

THE following cases of gunshot wounds (except Cases XV, XXXVII, XXXVIII, and XXXIX), were placed under my care twenty-four hours after a battle, during a recent revolution in Honduras, and while I was Surgeon-General of that country's army. From the time of the battle until my advent the cases had received no professional attention, and as retrograde changes are so largely facilitated by such fierce tropical heat as is there found, the deplorable condition of many of the wounded can hardly be imagined.

With the exceptions noted, the wounded were all in a building that had been assigned for hospital-purposes, and a brief description of which will not be out of place. It was an old "adobe" of two rooms, each twenty by twenty-five feet, and had been cleared out for the reception of the wounded men. Each room had three large double doors, no windows, a dirt floor, and whitewashed walls—that is, the walls had once been whitened, but it was many years before. The beds were made of raw-hide, stretched on a frame, and supported by posts at the four corners, and the bedding consisted of one blanket per man, except in the case of the Americans, and for them had been provided canvas beds and cotton sheets.

The medical and surgical armamentarium consisted of one operating-case, containing a fairly good assortment of instruments, chloroform, carbolic acid, mercuric chlorid, iodoform, morphin, and unbleached muslin. The muslin furnished lint, pads, "sponges," bandages, "drainage-tubes," and a rough sort of extension-apparatus. The dressings used were made by ravelling out the muslin, which was then dusted with iodoform, in some cases having been previously soaked in 5 per cent. carbolic-acid solution.

This report is submitted, not because of any originality in treatment that might possess intrinsic scientific value, but rather because the cases are many of them interesting in themselves, and because the unusual and unfavorable surroundings furnish added interest, as well as, perhaps, some indication of possible results under most discouraging circumstances. A raw-hide bed is better than the ground, and an adobe house is better than none at all—just as a shirt, a pair of trousers, and a blanket, though not quite so desirable as clean bedclothes and a clean nightshirt, are still better than nothing as covering for the patient.

The daily articles of diet were beef, beans, cheese, and a hard, dry corn-bread; but this food, with the exception of the beef, was all that they had been accustomed to. The beef was a luxury.

In most of the uncomplicated cases the path of the bullet was swabbed out with a 50 per cent. solution of carbolic acid, as it was found that this method of treatment induced a more rapid and satisfactory healing.

The cases are divided into wounds of the head (5), of the upper extremity (9), of the lower extremity (22), and of the trunk (4), and special attention is called to Cases I, III, VI, VIII, X, XXII, XXXV and XXXVI.

WOUNDS OF THE HEAD.

I. A. C. was an American, thirty-two years old. The bullet (probably from a Winchester thirty-eight caliber rifle) had entered half an inch to the right of the median line, and two and a half inches above the supra-orbital arch. The hair was shaved, and under chloroform-anesthesia a semicircular incision was made, including the upper margin of the wound, disclosing a ragged perforation of both tables. The bullet was found, in company with several spicula of bone, three-quarters of an inch below the surface of the cerebrum. These were removed after the wound had been enlarged slightly with forceps. All ragged edges were carefully trimmed away, and the wound was irrigated gently with warm water. About one-and-a-half fluidounces of cerebral matter escaped during the operation. The wound was carefully closed, and a silk-thread drain left in, which was removed on the third day. The patient rallied, and did well until the fourteenth day, when he was allowed to go out for a walk. He immediately got drunk, and lay in the hot sunshine all day. He was found and brought back in the evening, delirious, the temperature being 103°, and the pulse-rate 135. These conditions persisted until the seventeenth day. The wound was reopened, three drams of pus evacuated, and drainage reëstablished. The unfavorable symptoms were at once relieved, and the man went on to good recovery.

II. C. N., an Indian, was thirty-eight years old. A thirty-eight caliber Winchester, or revolver,

bullet, coming from above downward, had struck first about the nasal eminence, going from right to left, and had finally comminuted all the bones of the orbit, turning the eye upward upon the forehead. When first seen panophthalmitis and septic meningitis were well advanced, and nothing availed to save the life of the patient.

III. J. M. L. was an Indian, twenty-four years old. A small bullet entered at the articulation of the superior maxilla and the malar bone, on the right side, and passing backward and outward inside the zygoma and ramus of the jaw, and immediately below the external auditory meatus, made its exit through the mastoid portion of the temporal bone, which it finely comminuted. In cleaning the wound thirty-eight small pieces of bone, six pieces of lead, and sixty-four large maggots were removed. Frequent irrigation with a 1 : 3000 mercuric-chlorid solution kept the canal comparatively clean, and the case went on to good recovery in about four weeks, leaving, of course, resultant loss of vision and hearing, together with facial paralysis on the right side.

IV. J. B., an Indian, was thirty years of age, whose wounds were rather eccentric, and were made by a small bullet. The man must have had his mouth open when shot, for the ball had passed horizontally through both cheeks without injury to the teeth. The two small holes healed rapidly.

V. J. M. M. was an Irish-American, thirty-five years old. A bullet, probably from a Winchester rifle, passing from before backward horizontally, and a little above the temporal ridge, had gouged out about one-and-a-half inches of bone, splintering both tables, but affecting the inner more than the outer table. The wound was in a very bad condition, and during the removal of the bone-splinters, gravel, dirt, etc., a large amount of brain-substance was lost—probably two or three ounces or more. The patient never fully rallied, and died on the third day.

Of the five cases, one was very simple, and is mentioned merely as a curiosity. Of the remaining four, all serious, two recovered, giving 50 per cent. mortality.

WOUNDS OF THE UPPER EXTREMITY.

VI. E. H., an Indian, was twenty-one years old. In this case, as in many of the others, the position of the man at the time of receiving the injury is indicated quite conclusively by the nature of the wound or wounds. This soldier must have been standing with his left arm extended along the barrel of his gun, presumably aiming the weapon in the direction from which the bullets were coming, for a ball, probably from a Winchester rifle, had torn away both phalanges of the left thumb, and entered the arm just above the insertion of the deltoid, and about three-and-a-half inches below the shoulder-joint. There was no point of exit. Extending the arm and placing it in the position suggested as probable, a probe was introduced, and with ease passed directly into the thorax, the bullet having entered between the first and second ribs, passing in front of the shoulder-joint. Amputation of the thumb was completed, and expectant treatment decided upon for the more serious injury. On the third day pyo-pneumothorax was quite evident, and expectoration of almost pure pus commenced, the temperature ranging from 99° to 102°. This condition was maintained for about two weeks, when improvement began and continued until the fourth week, when the man was discharged.

VII. A. N., an Indian, was twenty-two years old. In this case the position occupied at the time of the injury was, probably, about the same as that of E. H., Case VI, with the arm extended, but the bullet had a much lower velocity, and did little damage. The point of entrance was three-and-three-quarter inches below the shoulder-joint; the bullet had passed in front of the joint, and was found in the pectoralis muscle, over the third rib. Rapid, uncomplicated recovery followed removal.

VIII. C. M. was thirty years old. The amount of injury in this case indicated a large bullet and a fairly high velocity—conditions furnished by the Remington (modello Argentino) rifles, many of which arms were in use. The position occupied was probably very similar to that in Cases VI and VII.

The ball entered the forearm posteriorly four inches above the wrist-joint, passing out anteriorly about three inches below the elbow, splintering and denuding both bones; it then entered the arm five inches below the shoulder-joint on its outer anterior aspect, passed over and behind the shoulder, and was removed from the trapezius, just over the spine of the scapula. The forearm was resected, but the result was most unsatisfactory, and on the thirteenth day the arm was amputated in the middle third. Satisfactory recovery followed.

IX. H. C., an Indian, was twenty-six years old. The wound in this case seemed to indicate a position similar to that occupied by Cases VI, VII, and VIII, for the bullet, a small one, probably from a Winchester rifle, entered the left arm about six inches below the shoulder-joint, passed in front of it, and was found embedded in the pectoralis muscle three inches to left of the median line and over the sixth rib. A rapid and satisfactory recovery followed extraction of the bullet.

X. Y. C., an Indian, twenty-two years old, presented an exceedingly interesting condition. In the right forearm, posteriorly and three inches above the wrist-joint, was the point of entrance of a bullet, apparently of thirty-eight or forty-four caliber. There was no wound of exit, and the arm exhibited a condition somewhat alarming. The forearm and lower third of the arm were greatly swollen, blackened, and covered with clusters of blebs about the size of a grape, and filled with purple-black, slightly viscid, ill-smelling fluid. There was a sharp line of demarcation about midway between the elbow-joint and the shoulder-joint, and the following measurements were taken:

Circumference of forearm, largest	16 inches
" " arm, below line of demarcation	18 "
" " " above " "	9 "

The temperature was 101°, the pulse 98, and the arm was the seat of most intense pain. A diagnosis

of gangrene seemed unquestionable, and immediate amputation was urged by the junior surgeon, but I determined to try a less radical treatment. Longitudinal and transverse incisions, from one-eighth to one-quarter inch deep, and one-half inch apart, were made from the line of demarcation to the wrist, resulting in very free bleeding and almost instant relief from the excessive tension and pain. About two and a half or three pints of blood and bloody serum escaped. The arm was covered with a loose, wet dressing, and the incisions repeated daily for three days. By the fourth day the swelling had almost disappeared, the size of the arm was nearly normal, and the elbow-joint was movable, though movement caused considerable pain. On the sixth day the position of the bullet was made out about three inches above the elbow posteriorly, but the missile was not removed until two months later. The man left the hospital on the twelfth day, at which time the entrance-wound was rapidly healing. He was seen seven months afterward, and reported perfectly well.

XI. L. S., an Indian, twenty-four years old, had been wounded in the right wrist, a large bullet having entered on the dorsal side, passing through, and entirely destroying the wrist-joint. The forearm was at once amputated in the lower third, but the man died. Death was probably the result of a very severe wound of the left thigh.

XII. M. G. was an Indian, thirty-three years old. A small bullet had passed through the soft parts of the left arm, doing no damage. Death was caused by another wound.

XIII. Gen. W., a Mexican, forty-nine years old, suffered from an uncomplicated flesh-wound of the right arm, the ball having passed three inches below the shoulder-joint and to the outer side of the humerus. Rapid recovery ensued.

XIV. M. L. was an Indian, thirty-six years old. A small bullet passed through the soft parts of the left arm, three inches above the elbow-joint and to the outer side of the humerus. Uncomplicated recovery followed.

Of these nine cases of wounds of the upper extremity two were fatal, death probably being caused by other and more severe wounds. In one case resection was tried, but was eventually followed by amputation. In the remaining cases expectant treatment was eminently satisfactory.

WOUNDS OF THE LOWER EXTREMITY.

XV. S. L., an Indian, thirty-seven years old, came under my care forty-eight hours after he had shot himself, with a 38-caliber revolver, in the right foot. The ball entered midway between the extremity of the outer malleolus and the posterior extremity of the os calcis, passed forward and inward, and was found below and between the third and fourth metatarsal bones, from which location it was removed through an incision on the outer side of the foot. Removal and free drainage and irrigation resulted in rapid subsidence of inflammation and speedy recovery.

XVI. J. S. S., an Indian, about thirty years old, was accidentally shot with a Remington rifle. He was sitting on the ground, and the bullet coming from above downward, entered the left thigh seven inches below the anterior superior spine of the ilium, and passed out one-half inch to the left of the anus. He died four hours after being shot. The shaft of the femur and the greater portion of the left innominate bone were finely comminuted.

XVII. S. L. was an Indian, thirty-five years old. A large bullet, probably from a Remington rifle, entered four inches above the left knee-joint posteriorly, passed downward and forward, splintering the femur, tibia, and fibula. Gangrene was well advanced, and high amputation was not successful in saving the man's life.

XVIII. I. L., an Indian, forty-two years old, was also wounded with a large bullet, which had in this case entered two-and-a-half inches below the knee-joint anteriorly, and passed out three inches above the joint posteriorly. Gangrene was already advanced, and amputation in the upper third of the thigh was followed by death in forty-eight hours.

XIX. P. A., a Mexican, twenty-four years old, seemed to be a more promising case. A small bullet—38 caliber—had passed almost horizontally through the right knee-joint, splintering slightly both femora and tibiæ, but when examined there were no symptoms of gangrene. With all the antiseptic precautions possible, the leg was amputated in the middle third of the thigh. Unfortunately, gangrene made its advent on the second day after the operation, and the patient died forty-eight hours later.

XX. J. C. was an Indian, twenty-four years old. A small bullet passed through the right leg, from before backward, two inches below the knee-joint. The tibia was splintered up into the joint. The wound was in bad condition, but probably gangrene had not commenced, and amputation in the lower third of the thigh was followed by a very satisfactory recovery.

XXI. J. M. was an Indian, twenty-six years old, whose wound was the product of a small-caliber bullet which had passed through the left thigh, entering anteriorly three inches above the knee-joint and passing out about one-and-a-half inches lower, posteriorly. The femur was splintered down into the joint. Amputation in the middle third of the thigh was highly successful, and the patient made a good recovery.

XXII. C. J., an Indian, twenty years old, presented an unusually interesting condition. A small bullet had entered the left thigh, three-and-a-half inches above the knee-joint, on its posterior and anterior aspect, taking a course downward, forward, and inward; *i. e.*, toward the knee-joint. Despite a most careful and persistent examination and probing, no bullet could be found. There was very little pain and soreness in and about the joint, which was freely movable; there was no abnormal temperature and practically no inflammation; it was therefore decided to await further developments. The entrance-wound healed rapidly and with very little slough, and the general condition

persisted for three weeks. Only on forced motion of the joint was there any pain, and this steadily decreased. On the twelfth day a small tumor was made out, lying below, behind, and to the inner side of the patella, perfectly movable and about three-quarters of an inch in diameter. On the twenty-third day this was cut down upon and found to be a small piece of bone, apparently chipped from the inner condyle of the femur. The bone was removed, and the wound closed by first intention. The patient was discharged ten days later, with slight stiffness of the knee-joint.

XXIII. C. D. was an Indian, sixteen years old. A small bullet—possibly from a Winchester rifle, 38 caliber—passed through the left thigh from behind forward, entering about seven inches above the knee and lodging in the superficial tissues, anteriorly, two-and-a-half inches below the anterior superior spine. The femur was fractured, and a small piece had been chipped off. This was with some difficulty removed, the leg dressed, and a crude extension-apparatus applied. It was very difficult to keep the leg in good position, but the resultant deformity was not marked—much less than had been anticipated.

XXIV. L. S. was a Mexican, twenty-four years old. A large ball had passed through the left thigh from before backward, seven inches below the great trochanter. There had been great shock and very much hemorrhage, and the patient did not survive an amputation.

XXV. M. G. was a Spaniard, thirty-three years old. The bullet in this case entered the left thigh anteriorly, about six inches above the knee-joint, the point of exit being posterior, two inches above the point of entrance. The femur was fractured, and two large and two small fragments could be found; the distal extremity was split, but not quite into the joint, and amputation was decided against. Three of the bone-fragments were removed; the fourth, being more firmly adherent, was not disturbed; and the leg was fixed as well as it was possible. Sloughing was rather free, but by the end of the third week had begun to decrease, when, unfortunately, the patient died of secondary hemorrhage during my absence.

XXVI. C. G. was an Indian, nineteen years old. A large bullet passing from below upward and inward, commencing at a point about three inches above the inner malleolus of the left leg, had broken and split both bones of the leg, and so lacerated all the soft parts that no relations could be found. Gangrene had commenced and was not checked by amputation in the lower third of the thigh. Death occurred on the third day.
